  - A prospective outcome comparison study of the Chrisman-Snook and modified Brostrom procedure by Hennrikus et al.5 demonstrated that both operations provided good or excellent stability in more than 80% of patients, but the Brostrom procedure resulted in higher Sefton scores and a statistically significant decrease in complications when compared to the Chrisman-Snook.
  - Recently, a case series on 31 patients by Bell et al.1 showed 91% good or excellent results 26 years after undergoing the Brostrom procedure.
  - Outcome assessment for thermal-assisted capsular modification for ankle instability has shown promise.
  - The senior author has pioneered the use of this technology for the treatment of ankle instability.
  - Initial early-term follow-up studies show clear improvement in patients, with an average increase in AOFAS hindfoot scores of greater than 25 points.
  - We have previously reported on 16 patients with average follow-up of 14.5 months. Good to excellent results were achieved by 80% of the patients.
  - Subsequent publications and presentations have mirrored these results.
  - Most recently Maiotti et al.7 reported on 22 patients with 32 months of follow-up. Nineteen of these 22 patients had good to excellent results and 21 of 22 returned to sporting activity.

COMPLICATIONS

- The most common complications after repair of the lateral ligament complex are nerve-related. The incidence of nerve complaints after surgery ranges from 7% to 19%.
  - In addition to nerve complications, wound complications and infection, stiffness, and deep venous thrombosis have been reported. These complications are of course present with all surgeries.
The possibility of recurrent instability is also a possible complication of surgery. This is most often a result of inadequate rehabilitation but can also result if the patient is not appropriately evaluated for hindfoot varus or connective tissue disease.

REFERENCES

DEFINITION
- Lateral ligament instability occurs in some patients after an inversion injury. Although an inversion injury is common, only a few patients have ongoing ankle instability severe enough to require surgery. Persistent instability may occur in 15% to 48% of patients.
- Lateral ligament disruption may occur in combination with osteochondral defects, hindfoot varus, peroneal tendon tears, anterior lateral joint impingement, or a tight heel cord. Any of these concomitant pathologies needs to be sought during the clinical examination and treated if it represents a significant component of the ongoing symptoms.
- Medial ankle instability may occur in combination with lateral ankle instability. In these cases the medial ligament instability may need to be addressed at the same time.

ANATOMY
- The lateral collateral ligaments include the calcaneofibular (CFL) and anterior talofibular ligaments (ATFL). These are condensations within the lateral capsule.
- The CFL runs from the anterior tip of the fibula to the lateral wall of the calcaneus. The ligament passes superficial to the lateral margin of the posterior facet of the subtalar joint and courses deep to the peroneal tendons to insert via a broad base onto the lateral side of the calcaneus.
- The ATFL arises from the anterior portion of the distal fibula and inserts onto the lateral side of the talar neck.

PATHOGENESIS
- Lateral ankle instability occurs after an inversion injury to the lateral ligament complex. The injury typically occurs in plantarflexion. Traditionally the ATFL ruptures first and the CFL second. A cavus foot may predispose the ankle to recurrent instability. Osteochondral defects of the talus and peroneal tendon tears are known associated pathologies.

NATURAL HISTORY
- Most ankle sprains resolve without the need for surgery. However, a recurrently unstable ankle treated with appropriate physical therapy protocols may benefit from lateral ankle ligament repair or reconstructions. Left untreated, persistent lateral ankle instability may result in fixed varus tilt to the talus within the ankle mortise and eventual ankle arthritis. Most patients present because of the disability associated with the recurrent sprains. Physiotherapy and bracing will improve symptoms in some patients with recurrent instability. There does not appear to be a role for immediate surgery on ruptures of the lateral ligaments.
The area of maximum discomfort and instability should be elicited. We take the ankle and hindfoot through a range of motion independent of one another to determine the joint of maximum discomfort.

Peroneal tendon pathology may accompany lateral ankle instability. A resisted contraction of ankle eversion should be performed and the tendons palpated for pain and fullness (suggestive of tenosynovitis). The peroneal tendons, which are flexors, are best isolated with the ankle in plantarflexion and testing eversion against resistance. Peroneal tendon weakness accompanies most peroneal pathology due to pain; marked weakness may signify a peroneal tendon tear. In our experience, the combination of chronic ankle instability, varus hindfoot, and marked peroneal tendon weakness should raise the suspicion for a peroneal tendon tear. Occasionally, an equinus contracture may be associated with lateral ankle instability. A Silfverskiold test (ankle dorsiflexion with the knee flexed contrasted with ankle dorsiflexion with the knee extended) allows the examiner to determine whether the contracture is isolated to the gastrocnemius or involves both the gastrocnemius and soleus components of the Achilles complex.

The ATFL resists anterior translation and medial rotation of the talus on the tibia. A direct anterior draw (pulling the talus anteriorly without plantarflexion and internal rotation) may fail to elicit instability in an unstable ankle as an intact deltoid ligament medially will prevent translation. Instead, the examiner should hold the tibia posteriorly with the left hand while translating the calcaneus anteriorly and internally rotating the foot at the same time. Side-to-side comparison to the contralateral, physiologically stable ankle assists in identifying ankle instability.

An inversion stress test determines the integrity of the CFL. An injury to the syndesmosis (ie, “high ankle sprain”) may be elicited with a squeeze test and by rotating and translating the talus in the ankle mortise in dorsiflexion. A syndesmotic injury must be distinguished from lateral ankle instability since treatment is different.

We also routinely examine the medial ankle for deltoid instability, since medial and lateral instability may coexist.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- We routinely obtain weight-bearing AP and lateral ankle radiographs; if more information is required, we add a mortise view. Osteochondral defects, anterior osteophytes, and tibiotalar arthritis associated with recurrent instability are generally visualized on standard radiographs of the ankle (FIG 2).
- On occasion we add a calcaneal axial view, Saltzman view, or tibial views if we need additional information on limb alignment. Recurrent ankle instability may be secondary to tarsal coalition; if the hindfoot is stiff on clinical examination, then calcaneal axial view and standard foot radiographs may identify the coalition. CT provides greater detail of osteochondral defects, osteophytes, arthritis, and tarsal coalition and should be obtained if these associated findings are suggested on plain radiographs.
- An MRI, particularly an MRI arthrogram, may provide detail of the deficient ligaments. Associated chondral and osteochondral defects as well as soft tissue impingement lesions may also be visualized by an MRI examination (FIG 3).
- Selective, diagnostic local anesthetic blocks of the ankle, subtalar, or talonavicular joints may be required to determine localized joint pain.
- When the diagnosis of ankle instability is suspected but remains in question, an inversion stress test done under fluoroscopy, compared to the physiologically stable contralateral ankle, may be useful. Bone scans can assist in determining associated pathology.

**DIFFERENTIAL DIAGNOSIS**

- Loose body in ankle
- Osteochondral defect
- Syndesmotic instability
- Peroneal tendinopathy or rupture
- Medial ankle instability
- Cavus foot
- Tarsal coalition

**NONOPERATIVE MANAGEMENT**

- Nonoperative treatment includes bracing and physiotherapy. Patients with recurrent ankle instability may develop peroneal tendon weakness and loss of proprioception.\(^{33,37}\) Physiotherapy via proprioceptive training and strengthening can resolve the ankle instability. Bracing may help a patient to recover from a sprain and prevent future sprains by strengthening the dynamic, stabilizing peroneal tendons. Nonoperative treatment is less effective if ankle instability is associated with fixed hindfoot varus. Flexible hindfoot varus may be compensated for with a

---

**FIG 2 • Radiologic finding of osteochondral lesion of talar dome.**

**FIG 3 • MRI finding of osteochondral lesion of posteromedial talar dome.**
lateral wedge orthotic. If hindfoot varus is driven by a planatarflexed first ray (as determined by the Coleman block test), then the orthotic should be “welled out” under the first metatarsal head, permitting further progression of the hindfoot into physiologic valgus.

**SURGICAL MANAGEMENT**

- The indication for surgical management of lateral ligament instability is chronic symptoms despite appropriate nonoperative management, including physiotherapy and bracing.
- Surgical management of lateral ankle ligament instability includes repair (anatomic tightening of the lateral ankle ligaments) and reconstruction (reconstitution of the lateral ankle ligaments using more than the local physiologic tissue in the lateral ankle ligamentous complex).
- Lateral ankle ligament reconstruction may be anatomic or nonanatomic. Anatomic reconstruction implies that the ligaments are rebuilt in the physiologically occurring orientation. Nonanatomic reconstruction suggests that lateral ankle support is reconstituted with tissue (typically tendon transfer to substitute for ligament deficiency) that does not follow a physiologic orientation of the ATFL and CFL.
- In our opinion, the literature on this topic favors anatomic over nonanatomic reconstruction; examples of nonanatomic reconstruction include the Evans and Watson-Jones procedures. We recommend repairing the lateral ankle ligaments when possible. However, if the ligaments are not repairable or require an augmentation, we perform an anatomic reconstruction. Graft options for reconstruction include autograft (peroneus brevis, plantaris, gracilis) or allograft tendon.

**Preoperative Planning**

- Plain radiographs, and if further detail is needed other imaging studies of the ankle, must be evaluated for associated conditions, such as malalignment, osteochondral defects, tendon pathology, and arthritis. Adjuvant procedures must be planned so that they may be safely performed in concert with ligament reconstruction.
- We recommend performing stress testing with the patient under anesthesia. In our opinion, the gold standard tests to determine lateral collateral ligament integrity are (a) open anterior drawer and (b) inversion stress test on the table to determine the integrity of the lateral collateral ligaments.

**Positioning**

- We routinely use a bean bag or large bump under the ipsilateral hip to rotate the operated extremity and allow full access to the lateral ankle (FIG 4).
- A full lateral position is avoided, as it limits access to the proximal medial tibia, making harvest of the gracilis tendon autograft more challenging.

**Approach**

- We recommend an extensile approach (ie, a longitudinal curvilinear approach) in lieu of the traditional J-shaped incision popularized by Brostrom. The extensile approach affords access to not only the lateral ankle ligaments but also the distal tibia, peroneal tendons, sinus tarsi, and lateral calcaneus for adjuvant procedures that may be warranted.

**GRACILIS RECONSTRUCTION THROUGH DRILL HOLES**

- We prefer a gracilis autograft tendon, anchored via drill holes, for the anatomic lateral ankle reconstruction and aim to obtain (a) immediate stable fixation, (b) biologic ingrowth to bone in time, and (c) an anatomic reconstruction. The technique is a modification of the plantaris reconstruction described by Anderson (TECH FIG 1).
- Place the patient on the operating table with the operative hip as described above. Apply a wide thigh tourniquet. Prepare and drape the leg to just above the knee. Perform anterior drawer and inversion stress tests on the table to confirm the diagnosis.
- Use regional anesthetic blocks if possible to ensure appropriate postoperative pain relief.
- If intra-articular pathology has been preoperatively identified or is suspected, we routinely address this with ankle arthroscopy before lateral ankle reconstruction (TECH FIG 2).
- Start the extensile longitudinal lateral incision on the distal fibula, continue it over the lateral malleolus, and curve it anteriorly toward the sinus tarsi (TECH FIG 3).
- Expose the superior extensor retinaculum anterior to the fibula while protecting the deep branch of the peroneal nerve, which has variable anatomy. Strip the extensor

TECH FIG 1 • Free gracilis lateral ligament reconstruction.

TECH FIG 2 • Osteochondral defect of the talus found on arthroscopy before ligament reconstruction.

TECH FIG 3 • Lateral incision (solid line) with course of sural and superficial peroneal nerves marked (dotted lines).

TECH FIG 4 • Lateral dissection anterior to the fibula, sparing the anterior talofibular ligament.

TECH FIG 5 • Open anterior drawer test. Talus is anterior and internally rotated relative to fibula, indicating a positive test and insufficiency of the anterior talofibular ligament.

Retinaculum off the fibula so that the extensor compartment is exposed. Carry the dissection distally toward the ankle joint to the junction between the tibia, talus, and fibula. Open the joint at this level. This dissection will ensure that no ligaments are damaged during the exposure (TECH FIG 4).

- Remove anterior osteophytes using an osteotome.
- Perform an open anterior drawer and inversion stress test (TECH FIG 5) to assess the integrity of the lateral collateral ligaments as a final check before proceeding with reconstruction. I will perform a repair if the ligaments are clearly torn off bone, if they are not obviously scarred or thickened, if there is enough length to bridge the gap, or if they have been avulsed with a bone fragment.
- If the ligaments are not considered repairable, then reconstruction is warranted. We favor an autograft gracilis reconstruction, and therefore optimal patient positioning and preparation and draping of the operated extremity are important.
- Perform a standard gracilis tendon harvest with an incision over the medial aspect of the tibial tubercle at the pes anserinus insertion. Carry dissection down through the sartorius fascia and onto the gracilis tendon. Isolate the gracilis with the knee flexed, and use a tendon stripper to release it from its muscle proximally. Reef the tendon using a baseball whipstitch.
Divide the tendon at its insertion into bone and measure it. Select a drill bit matching the size of the tendon (typically a 3.5-, 4.5-, or 6-mm drill bit). Alternatively, a tendon-anchoring interference screw system may be used, size-matched to the harvested tendon’s diameter.

Expose the fibula first by removing part of the peroneal fascia so that the peroneal tendons and the posterior fibula are exposed (TECH FIG 6). We typically examine the peroneal tendons at this time to rule out or treat associated peroneal tendon pathology. If needed the peroneal retinaculum is incised with a step cut to allow complete exposure of the peroneal tendons for débridement or repair.29

Incise the collateral ligaments and expose the insertions of the CFL and ATFL. Dissect to the origin of both ligaments on the calcaneus and talus. Both areas are dissected clear onto bone (TECH FIG 7). Use a curette to clear the area of the junction of the body and neck of the talus.

Make a medial incision at the anterior border of the Achilles tendon, and carry dissection down to the bone and tendon at this level (TECH FIG 8).

Drill through the calcaneus from medial to lateral, adjacent to the Achilles tendon, with the appropriately sized drill bit (depending on harvest tendon diameter), exiting laterally at the origin of the CFL (TECH FIG 9). A cannulated drill or a combined aiming device can be used to target this drill to the calcaneofibular footprint on the calcaneus.

Make a fibular drill hole starting at the insertion of the CFL and exiting the posterior fibula. Make another fibular drill hole starting at the insertion of the talofibular ligament and exiting in the posterior fibula about 1 cm above the exit point of the previous fibular drill hole (TECH FIG 10).

Then, make a 2.5-mm drill hole in the center of the junction between the talar body and neck (TECH FIG 11). Measure its depth. A fully threaded cancellous small-fragment screw with a small- and large-fragment washer is readied on the back table.

With a no. 2 braided nonabsorbable polyester suture, suture the tendon onto the edge of the Achilles medially,
using a Kessler stitch on the nonbraided end of the gracilis tendon. Leave 1 cm of loop between the Achilles and the end of the gracilis to prevent buildup of suture and ligament medially, which may cause irritation. Place the knot in the middle of this segment.

- Use a tendon passer to pass the tendon graft through the calcaneal tunnel to the lateral calcaneus.
- Cycle the tendon a few times to make it tight.
- Pass the tendon through to the posterior aspect of the fibula and pull it tight with the ankle in eversion. Suture the tendon to any remaining tissue on the fibula (TECH FIG 12).
- Bring the tendon back through the fibula so that it exits anteriorly at the second drill hole.
- Cycle the tendon in tension and suture it to the cuff of tissue on the fibula at the insertion of the talofibular ligament.
- Start the selected small-fragment screw with the large and small washer into the 2.5-mm hole in the talar neck.

- Place the split tendon end over the washer (right side) and under the washer (left side) and secure it around the washer in a clockwise direction. Hold the foot in dorsiflexion and eversion.
- Hold the tendon tight around the washer and screw and tighten the screw home. The tendon will tighten as the screw is placed home (TECH FIG 13). Although interference screw systems are effective, our method using standard screws and a simple ligament washer is cost-effective and consistently affords immediate ankle stability.
- Suture the free end of the tendon back onto the tendon segment between the fibula and washer.
- Suture the remainder of the tendon back onto the lateral side of the fibula, and trim the residual tendon end.
- To confirm stability and proper ligament tension of the reconstruction, place the ankle through repeat open anterior drawer and inversion stress tests. Close the wounds using nylon or staples. Use of a drain is at the surgeon’s discretion.
COUGHLIN DRILL HOLES IN BONE

- An alternative technique is to use drill holes through the bone made on the lateral side only.\textsuperscript{14} This is a variation of the Emslie technique (TECH FIG 14).
- Use a similar exposure, with no medial incision.
- Make two drill holes on the lateral wall of the calcaneus on each side of the origin of the CFL.
- Pass the tendon through the drill holes and suture it back onto itself.
- Make a single drill hole on the tip of the fibula joining the insertion of both lateral collateral ligaments.
- Make two drill holes on each side of the insertion of the talofibular ligament.
- Pass the tendon through the fibula and through the drill holes on the talus, and tension it and suture it back onto itself.
- We consider this variation more challenging than our described technique, specifically in passing the tendon through bone without fracturing the bone bridges. Moreover, we find it more difficult to ensure anatomic location of the ligaments and optimal tendon tensioning. In our opinion, prolonged postoperative immobilization may be required, depending on the strength of the bone bridges.

BIOTENODESIS SCREW TECHNIQUE

- With this technique a similar exposure and tendon harvest are used (TECH FIG 15). No medial exposure is required.
- Make a drill hole on the lateral side of the calcaneus at the CFL origin. Place the tendon over the tip of a tenodesis screw and secure it to the lateral wall of the calcaneus.
- Pass the tendon through two fibular tunnels at the anatomic locations of the CFL and talofibular ligament, exiting over a posterior fibular bone bridge as described in our technique.
- Make a second drill hole on the lateral side of the talus at the junction of the body and neck to accommodate the tendon and a second biotenodesis screw.
- Our concerns with this alternative are (a) quality of fixation via interference screw in the relatively weak cancellous bone of the calcaneus and (b) the relatively large talar drill hole, which may serve as a stress riser and cause of talar neck fracture.

MYERSON MINIMAL INCISION TECHNIQUE

- This technique (TECH FIG 16) is similar to the Coughlin technique but is performed through two small incisions.
- Make one incision over the calcaneal drill holes and a second over the region of the talar drill holes. Carry dissection down to bone. Make two connecting drill holes in each location. Tunnel a drill bit and guide subcutaneously to drill the pathway through the fibula.
- Harvest the graft and route it in the same fashion as in the Coughlin technique described earlier.
- While this is a reasonable alternative, as for the Coughlin technique, we have difficulty passing and tensioning the tendon using this technique.
PEARLS AND PITFALLS

**Exposure**
- Ensure that the exposure goes through the anterior compartment and down into the ankle. This will avoid damage to the ligaments before the open anterior drawer test.

**Positioning**
- Use a bean bag to ensure that the ankle is internally rotated to allow access to the lateral side of the ankle. Different patients have different amounts of internal rotation, and this needs to be accommodated. However, avoid a full lateral position if you plan a gracilis tendon harvest.

**Drill holes**
- Drill the calcaneal hole from medial to lateral. The vector guide can be used to ensure correct positioning of the exit hole and the CFL footprint on the lateral calcaneus.

**Drill hole size**
- The drill hole should closely match the size of the graft to ensure osseous integration. The drills and taps from the anterior cruciate ligament set can be used. The drill hole should be large enough to pass the tendon.

**Graft preparation**
- The graft should be prepared with a whipstitch to ensure that it passes easily through the bone tunnels.

**Graft tensioning**
- Avoid anterior translation of the talus within the ankle mortise when the tendon reconstruction is tensioned. In particular, place a bump under the distal tibia and avoid placing a bump under the heel, which tends to translate the foot and talus anteriorly. Also, after each pass of the tendon through a tunnel, cycle the ankle with the tendon under tension to gain optimal final tension.

POSTOPERATIVE CARE
- With our preferred technique, patients are placed in a walker boot at the time of surgery. At 1 week they are allowed to bear weight as tolerated. The sutures are removed at 2 weeks. Ankle range of motion, supervised by physiotherapy, is initiated at this time. Patients are kept in the walker boot until 10 weeks after surgery during weight bearing. Gait training is started 8 weeks after surgery. Proprioception and single toe raises are started 12 weeks out. Patients may return to sports after 4 months.

OUTCOMES
- There are few retrospective reviews of anatomic reconstructions using various autografts. Despite the paucity of literature all studies have reported good results, with 88% to 100% of patients reporting good outcomes.\(^1,12,15,46\)
- Few studies have specifically looked at the outcome of a gracilis ligament reconstruction. A review of 29 ankles in 28 patients by Coughlin reported a successful outcome in terms of AOFAS and Karlsson scores in all patients. Postoperative follow-up averaged 23 months.\(^15\)
- Sammarco and DiRaimondo used a portion of peroneus brevis through drill holes; 91% good and excellent results were seen in 43 ankles.\(^44\)
- One study looked at the outcome of a semitendinosus graft reconstructing the ATFL; 81% of 23 patients reported an improved outcome.\(^41\)
- There are sufficient studies with poor outcomes in the literature to recommend against nonanatomic reconstruction of the lateral ankle ligaments. Eleven papers in a recent review of lateral ligament reconstructions argued against nonanatomic reconstruction, including the Evans and Watson-Jones procedures.\(^6,8,22,24,25,28,33,36,37,40,47\)

COMPLICATIONS
- Wound healing
- Recurrent instability
- Nerve injury
- Loss of range of motion
REFERENCES

DEFINITION
- Lateral ankle sprains are the most common injury in sports, accounting for 15% to 20% of all athletic injuries in some parts of the world. These injuries result in compromise or complete disruption of the lateral ankle, and, often subtalar, ligamentous complexes.\textsuperscript{12,15}
- Ankle sprains range in severity from mild stretching to complete disruption of the ligamentous structures. Often, the injuries of moderate or medium severity are the most difficult to accurately diagnose and, therefore, manage properly.
- Most acute ankle sprains respond well to a course of nonoperative therapy, including standard rest-ice-compression-elevation (RICE) methods, functional bracing, and even immobilization followed by physical therapy.
- From 30% to 40% of patients will have persistent problems related to pain and swelling for up to 6 months after the injury, and 10% to 20% will have difficulties with recurrent sprains, leading to chronic ankle instability.\textsuperscript{10}
- Chronic ankle instability usually manifests itself in one of two ways: (1) recurring symptoms after an acute episode of ankle sprain, or (2) a pervasive feeling of looseness or “giving way” without warning.

ANATOMY
- The lateral ankle ligamentous complex is made up of three distinct ligaments: the anterior talofibular, the calcaneofibular, and the posterior talofibular ligaments. Other structures contributing to overall lateral ankle stability are the inferior extensor retinaculum and subtalar ligamentous complex.
- The anterior talofibular ligament (ATFL), which blends with the anterolateral joint capsule, is 15 to 20 mm long, 6 to 8 mm wide, and 2 mm thick.
- The ATFL originates from the anterior and distal fibula to insert on the lateral body of the talus, forming an angle of about 75 degrees to the floor.
- The calcaneofibular ligament (CFL) is 20 to 30 mm long, 4 to 8 mm wide, and 3 to 5 mm thick. It originates from the posteromedial portion of the inferior fibula to travel within the peroneal tendon sheath, under the tendons, and attaches to the lateral wall of the calcaneus. The orientation is 10 to 45 degrees posterior to the longitudinal axis of the fibula. The angle formed between the ATFL and CFL is 100 to 105 degrees.
- The posterior talofibular ligament (PTFL) is the largest of the lateral ankle ligaments, at 30 mm in length, 5 mm in width, and 5 to 8 mm in thickness. It has a broad insertion on nearly the entire posterior lip of the talus.
- The ATFL has the lowest load to failure of the three ligaments. Conversely, it has a much higher capacity to withstand strain than the CFL or PTFL, thereby allowing the greatest deformation before failure of all three structures.\textsuperscript{16}
- The ATFL is taut with the ankle in plantarflexion, whereas the CFL is relatively loose. The reverse is true for the dorsiflexed ankle. The strength of the CFL and the stability afforded by the bony mortise at the malleoli in a neutral or dorsiflexed ankle make maximal plantarflexion the position of vulnerability for lateral ankle ligament injuries.\textsuperscript{1,2}
- The subtaligamentous structures include the lateral talocalcaneal ligament, cervical ligament, interosseous talocalcaneal ligament—thought to provide the greatest contribution to stability of the subtalar joint, and the calcaneofibular ligament. These provide some measure of stability to the lateral ankle.

PATHOGENESIS
- Ankle instability is thought to be either acquired, as a result of repetitive trauma, or inherited due to ligamentous laxity, biomechanical abnormality (eg, heel varus, cavus foot position), or a combination of both.
- The ATFL is most commonly injured, accounting for about 75% of injuries to the ligaments of the ankle, followed by the CFL, which accounts for about 20% to 25% of these injuries. Injury to the ligaments occurs when they are either stretched or completely torn, either by avulsion from bone, or, more commonly, from midsubstance tearing.
- Neuromuscular deficits also result from these inversion injuries, leading to slower firing of the peroneal muscles in response to inversion stress, decreased responsiveness in the peronal nerve branches, weakness, and restricted dorsiflexion range of motion due to inadequate muscle forces.
- Repetitive injury can result in accumulated scarring leading to anterolateral mechanical impingement or even sinus tarsi involvement.\textsuperscript{5,14}
- Subtaligamentous ligaments may also be injured, although usually to a lesser extent.

NATURAL HISTORY
- Even though most ankle sprains and instability receive some form of treatment, there is little consistency in treatment regimens. The natural history is sketchy as to what would happen in the truly untreated situation.
- In one long-term study, one third of patients treated functionally for ankle sprains had continued complaints of pain, swelling, or instability in the form of recurrent sprains.\textsuperscript{10}
- Nearly three fourths had some level of impairment on return to sporting activity, with almost 20% incurring repeated sprains and 4% with pain at rest or severe disability.
- Dysfunction after an acute sprain will persist for 6 months in 40% of injured athletes.\textsuperscript{5}
- While it has been suggested that long-term lateral ankle instability and repeated traumatic events to the ankle can lead to advanced stages of degenerative disease, there is no actual proof of this theory.
- Nevertheless, it is presumed that continued ankle injuries as a result of lateral ankle instability can, and often will, lead to osteochondral injuries, abnormal joint mechanics, and neuromuscular dysfunction, predisposing the individual to risk of...
more severe injury to the extremity or disabling degenerative arthritis of the ankle and, possibly, the subtalar joints.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- Patients experiencing acute ankle sprains often describe a painful tearing or pop after sustaining an inversion type injury. Longer-standing instabilities will cause complaints of lack of confidence in the joint under high demands or frequent giving way; pain and swelling often are less severe and are of secondary concern to the patient.
- Findings on examination in the acute situation are reliably present and include anterolateral ankle pain, swelling, and pain on passive plantarflexion or inversion. In the patient with a chronically unstable ankle, the examination focuses more on the anterior drawer and talar tilt tests and the “suction sign.”
- Assessment for structural abnormalities also is important. Heel position should be examined in every patient, by looking at the patient from behind while he or she is standing, to determine the possible presence of varus malalignment.
- Neuromuscular function is another important part of the examination. Peroneal muscle group function, specifically, is critical. Strength and stability of the peroneals should be assessed by resistive muscle grading against plantarflexion and eversion. Provocative maneuvers such as the plantarflexion eversion stress test also should be performed to ensure that the peroneal tendons do not subluxate from the retrofibular groove.
- Sensory nerves should always be inspected to ensure no neurapraxia has taken place as a result of the traction from the injury.
- Syndesmotic integrity should be tested with palpation, the “squeeze” test, and dorsiflexion–external rotation provocative manipulations.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- According to the Ottawa Ankle Rules,^^1^ nearly 100% sensitivity is approached if the following criteria are used in the acute setting:
  - Tenderness at the posteroanterior edge or tip of the medial or lateral malleolus
  - Inability to bear weight (4 steps) right after the injury or in the emergency room
  - Pain at the base of the fifth metatarsal
- If radiographs are required, anteroposterior, lateral, and mortise views, preferably weight bearing, should be performed, looking for avulsion fractures of the tip of either malleolus, or, less frequently, the lateral calcaneus. One also should inspect for osteochondral fractures, joint malposition, and other fractures that may mimic lateral ankle sprains (see Differential Diagnosis).
- Stress views can be obtained in either the AP (talar tilt) or lateral (anterior drawer) position. Performing the study while stressing the ankle (as described in the section on examination of the patient) can give meaningful information regarding the stability of the joint. Significant controversy exists on what constitutes an abnormal study, but on the basis of the cumulative review of literature on this topic, more than 15 degrees of varus tilt and 5 mm of anterior translation are reasonably considered abnormal.
- MRI is valuable for determining whether the ligamentous structures have been injured and in what stage frame. Attenuation, wavy fibers, or disruption in the face of fluid accumulation suggests recent injury, whereas thickening or intrasubstance signal change gives rise to suspicion for a more remote injury. Infrequently, an absence of ligament tissue is noted, reflecting repeated injuries leading to degeneration of the complex.

**DIFFERENTIAL DIAGNOSIS**
- Acute
  - Lateral malleolar fracture
  - Fifth metatarsal fracture
  - Lateral talar process or “snowboarder’s” fracture
  - Peroneal tendon dislocation
  - Osteochondral defect
  - Superficial peroneal neurapraxia
- Chronic
  - Peroneal instability
  - Peroneal split tears
  - Subtalar instability
  - Osteochondral defect
  - Tibiotaral or subtalar arthritis

**NONOPERATIVE MANAGEMENT**
- Nonoperative management is the mainstay of treatment for both acute and chronic instabilities. Most patients will respond to conservative management; consequently, it is essential that appropriate conservative treatment be tried for all patients before surgery is suggested.
- Acute swelling and pain, whether from a new injury or recent repeat injury, is best managed with RICE. Immobilization in a walking cast or boot should be considered for anyone demonstrating a positive drawer or talar tilt after an acute episode or recurrence.
- Once the acute symptoms have subsided, functional strapping, taping, or bracing should be instituted along with an exercise regimen emphasizing peroneal strengthening, proprioceptive training, and Achilles tendon stretching.
- In the patient with a chronically unstable ankle, shoe wear modifications can be added as the individual returns to sports or activities. Orthoses with lateral heel and sole wedges or flare on the lateral sole of the shoe can promote a valgus moment and help avoid injury in the vulnerable patient. Reducing heel height and stiffening the sole of the shoe also can be helpful.
- Prophylactic brace wear or taping has been shown to have some benefit in prevention of injury. It also has a positive effect on reduction in severity of sprains if reinjury occurs while these measures are in effect.

**SURGICAL MANAGEMENT**
- Surgery rarely is indicated for an initial acute injury.
- Acute injuries failing appropriate conservative care, in our opinion, are best treated with an anatomic repair and reinforcement using a modified Brostrom procedure.
- Chronic instability failing appropriate conservative measures is more complex.
  - In a previously unoperated patient with MRI evidence of tissue remnants, an anatomic repair (modified Brostrom procedure) is very effective.
In patients who have repeated injuries and are left without evidence of ATFL or CFL remnant by MRI, or in patients who have previously undergone an attempt at surgical correction, reconstruction with free tendon graft is our preferred method.3,4,7,13,17

Preoperative Planning

- All imaging studies, including MRI, are reviewed, and any adjunctive pathology that may need to be addressed at the time of surgery, such as fragments of bone, OCLs, or peroneal tendon pathology, is noted.
- The joint (and the contralateral joint) is examined under anesthesia to determine the true nature of instability and also to gauge the effect of the repair (FIGS 1 AND 2).
- Graft choice also is an important preoperative consideration. An autogenous hamstring graft can be chosen and harvested in similar fashion to that of ACL graft harvests.3,4,7,13,17

Positioning

- The patient is placed in the supine position, typically with an ipsilateral hip roll to allow access to the posterolateral corner of the ankle.
- Arthroscopic examination is performed to identify any unseen intra-articular pathology.9 A thigh holder and soft tissue ankle joint distractor often are necessary for the initial portion of the procedure.

Approach

- One of two approaches may be chosen, depending on the degree of pathology that is to be addressed.
  - For ankle ligament reconstruction alone, an anterior curvilinear incision bordering the distal inferior tip of the fibula is preferred.
  - If it is necessary to address peroneal pathology or anterior osteophytes, a more extensile lateral malleolar incision, curving distally after the tip of the fibula, is useful (FIG 3).
- An oblique incision over the calcaneus usually can be added to either approach without great concern for increased wound morbidity.

TALAR TUNNEL PLACEMENT

- The lateral ankle is exposed by one of two incisions, as previously described.
- The origin sites of both ATFL and CFL are identified (TECH FIG 1A).
Dissection proceeds to expose the insertion of the ATFL on the lateral talus just at the corner of the lateral process as it blends from the body to the neck (TECH FIG 1B,C).

A 15- to 20-mm tunnel is drilled horizontally at this point with a 4.5- to 6-mm drill to accept the first limb of the tendon graft (TECH FIG 1D,E).

FIBULAR TUNNEL PLACEMENT

The fibula is exposed and a 4.5- to 6-mm tunnel is drilled from the insertion of the ATFL through the posterior fibular cortex (TECH FIG 2A–C).

A second tunnel is made more distally from the CFL insertion to a point about 3 to 4 mm distal to the previous exit point on the posterior fibular cortex. This allows for graft passage over a cortical bridge, and, in addition, the graft can be sutured to periosteum to prevent sliding (TECH FIGS 2D–F AND 3).

An alternative method uses a single tunnel from a point between the ATFL and CFL insertions, not violating the posterior cortex, that would accept a folded or doubled graft fixed with a single interference screw within this single tunnel.
C. Reaming of the first tunnel is done with a size-matched reamer based on screw size and graft diameter. D. A second guide pin is inserted from the CFL origin, aiming superior and posterior, but 3 to 4 mm below the previously created tunnel. Care must be taken to avoid tunnel blowout. E. Reaming the second fibular tunnel. F. A bony bridge is preserved between fibular tunnels.

TECH FIG 3 • Postoperative non-weight-bearing radiograph after reconstruction of lateral ligaments with allograft.

CALCANEAL TUNNEL PLACEMENT

A tunnel of similar size is then drilled bicortically through the lateral calcaneal wall at the level of the CFL insertion (TECH FIG 4).

TECH FIG 4 • A. The guide pin for the calcaneal tunnel is placed with the peroneal muscle group swept posterior. The tunnel is placed just inferior to the insertion point of the CFL. B. Verification of tunnel position. (continued)
TECH FIG 4 • (continued) C. Reaming the calcaneal tunnel. D. Note the relation between the calcaneal insertion of CFL and the reamed tunnel.

**GRAFT PASSAGE**

- The sutured tendon is inserted first into the talar tunnel and fixed with an interference screw (TECH FIGS 5 AND 6).
- It is then woven through the fibular tunnel from the ATFL insertion, through the more proximal posterior exit tunnel, back through the more inferior fibular hole and out the CFL origin. This gives the most anatomic origin and insertion points (TECH FIG 7 A–C).
- Lastly, the graft is passed through the calcaneal tunnel.
- The foot is held neutral to slightly everted, and a roll of towels is placed under the calf to allow a slight posterior drawer effect. The graft is held taut as it is brought through the skin on the medial side (TECH FIG 8).
- A second interference screw is placed in the calcaneus (TECH FIG 9).
- Range of motion and stability are assessed. If tension does not feel appropriate, the calcaneal screw can be removed, the graft retensioned, and the screw replaced.
- The tendon can receive a few sutures at the fibular tunnels to maintain tension of the individual limbs representing ATFL and CFL (TECH FIGS 10 A,B AND 11).
- If the surgeon prefers the single fibular tunnel technique, the interference screw is placed in the fibula with one limb of the graft directed toward the talus (ATFL) and one to the calcaneus (CFL). These are then similarly tensioned and fixed with individual interference screw fixation. This method is more exacting, as the limbs of tendon must be cut to exact length and fit into the proper depths of their respective tunnels.

TECH FIG 5 • A. All tunnel holes are reamed in advance of graft passage. B. Allograft tendon is mounted for insertion into the tibia tunnel with the first interference screw. C. The graft is inserted into the talar tunnel and fixed by interference screw.
TECH FIG 6 • Schematic of interference fit tenodesis screw.

TECH FIG 7 • A. The graft is pulled through the first fibular tunnel by a previously placed pull-through suture weave. B. The graft is then pulled through the second fibular tunnel and tension maintained. A stay suture can be placed in the graft and the fibular periosteum to maintain the ATFL tension. C. Graft pulled through both tunnels.

TECH FIG 8 • A Beath pin is used to pull the suture through the medial side of the tunnel and then out through the skin for final tensioning.

TECH FIG 9 • After appropriate positioning of the ankle and tensioning of the graft, the calcaneal interference screw is inserted.
WOUND CLOSURE

- Layered closure is performed, usually with a subcutaneous layer of 2-0 Vicryl or monocryl followed by skin sutures with 3-0 nylon.

CALCANEAL OSTEOTOMY

- If heel varus is present, a laterally based closing wedge calcaneal osteotomy may be performed.
- An oblique incision is carried out directly over the area of the planned osteotomy (usually about 2 cm posterior to any other concurrent incision).
- Periosteum is raised in each direction.
- A 1- to 1.5-cm width is marked on the lateral wall of the calcaneal tuberosity verifying that the osteotomy will not breach the bone tunnel.
- Saw cuts are made convergently to meet just before violating medial cortex.
- The wedge is removed and the osteotomy closed.
- Fixation can be achieved through either a large axially directed screw or staples.

PEARLS AND PITFALLS

| Graft handling | Great care must be taken in harvesting autograft so as to get enough length on the native gracilis. |
|               | If allograft is used, it must be ordered properly, with enough length to span the distance of the tendon weave (25 cm is plenty). |
|               | Once the allograft is thawed, it should be bathed in antibiotic solution until ready for use. |

| Tunnel placement | Avoid tunnel breakout. |
|                 | Consider making two separate tunnels on the posterior fibula divided by a cortical bridge between them. This will help resist the chance of graft migration on cancellous bone within the V-shaped tunnel. |
POSTOPERATIVE CARE

- Bulky, padded splinting in neutral positions are maintained for 10 to 14 days postoperatively.
- Once wounds are healed satisfactorily, the patient may begin protected weight bearing in a cast, as tolerated, for another 4 weeks.
- Gradual transition from cast to boot and introduction of range of motion begin 5 to 6 weeks after surgery.
- Rehabilitation is then instituted focusing on restoration of motion, Achilles stretching, proprioceptive training, and peroneal strengthening.
- Athletic activity usually is withheld for 4 to 6 months.

OUTCOMES

- Anatomic reconstruction for failed acute and chronic instability patterns continues to be our preferred method of lateral ankle ligament reconstruction. This has been shown in the literature to be extremely successful for return to function and reduction or elimination of symptoms in appropriately selected patients.
- When a patient has lost reliable lateral soft tissue structures by virtue of repetitive injury or previous failed procedures, an anatomic free graft lateral ligament reconstruction provides a very good alternative.
- Reconstruction using this method reconstitutes the ATFL and CFL, thus providing restoration of both ankle and subtalar stability.
- Anatomic reconstruction coupled with the preservation of native peroneal tendon function provides an optimum environment for return to function.
- Paterson et al13 showed 81% complete or substantial symptom resolution in 26 patients at 2-year follow-up by performing reconstruction of the ATFL alone. No significant differences were noted between operated and contralateral ankles with respect to range of motion or uniaxial balancing.
- Coughlin et al14 reported on 2-year follow-up in 28 patients. All patients were rated to have good or excellent outcomes with objective improvement in talar tilt measurements (13 degrees pre- vs 3 degrees postoperatively) and anterior drawer testing (on average, 10 mm pre- vs 5 mm postoperatively).
- Addition of tenodesis or interference screw fixation adds the advantage of being able to promote range of motion earlier with less concern for graft loosening.8,17

COMPLICATIONS

- Nerve injury
- Wound problems
- Infection
- Joint stiffness
- Deep venous thrombosis
- Subjective under- or over-tightening

REFERENCES

DEFINITION

- Lateral ligament injuries of the ankle are treated conservatively with good results in most cases. However, several factors may lead to chronic ankle instability with recurring ankle sprains:
  - Inadequate primary treatment
  - Incomplete healing of the ligaments
  - Repetitive trauma with deteriorated tissue quality
- Patients with chronic ankle instability can be divided into two groups:
  - Patients with sufficient tissue quality to perform a local repair
  - Patients with inadequate tissue quality for a local repair
- A Broström procedure for lateral ankle reconstruction is possible, as long as there is sufficient tissue.
- In patients with insufficient local tissue, an augmentation is needed to rebuild or reinforce the lateral ligaments. There are different options of tendon grafts, each with certain advantages and disadvantages:
  - Tenodesis
  - Semitendinosus tendon or gracilis tendon
  - Plantaris longus tendon

ANATOMY

- Laterally, the ankle is stabilized by the anterior (ATFL) and posterior (PTFL) fibulotalar ligament and the calcaneofibular ligament (CFL) (FIG 1).5
- Additional stability is provided by the bony structures. Especially in dorsal extension, the talus is locked between the medial and lateral malleolus.

PATHOGENESIS

- Torn lateral ligaments are the result of an ankle sprain. Depending on the severity of the sprain, one to three of the lateral ligaments are injured. A rupture of the ATFL is involved in most cases.
  - Anatomic classification
    - Grade I: ATFL sprain
    - Grade II: ATFL and CFL sprain
    - Grade III: ATFL, CFL, and PTFL sprain
  - AMA (American Medical Association) standard nomenclature system by severity
    - Grade I: Ligament stretched
    - Grade II: Ligament partially torn
    - Grade III: Ligament completely torn
  - Grading by clinical presentation symptoms
    - Mild sprain: minimal functional loss, no limp, minimal or no swelling, point tenderness, pain with reproduction of mechanism of injury
    - Moderate sprain: moderate functional loss, unable to toe rise or hop on injured ankle, limp when walking, localized swelling, point tenderness
    - Severe sprain: diffuse tenderness and swelling, crutches preferred by patient for ambulation
- With each ankle sprain, proprioception of the ankle joint is compromised.
- The risk for another ankle sprain increases after each injury. In an uninjured person, an ankle sprain will occur in 1:1,000,000 steps. This risk increases to 1:1000 steps after a severe ankle sprain.11
Chronic ankle instability is the combination of insufficient active and ligament stabilization mechanisms. There is some evidence that special anatomic variations increase the risk of developing chronic ankle instability after an injury. The healing of the ligaments can be compromised by synovial fluid between ligament and bone (Fig 2).

**Natural History**

Chronic instability is a risk factor for degenerative arthritis of the ankle joint. Valderrabano et al. have shown an increased prevalence of arthritis in patients with chronic ankle instability. Recurrent ankle sprains are likely in the future, but this is strongly dependent upon lifestyle and sports activities.

**Patient History and Physical Findings**

The patient history includes sustained injuries, frequency of ankle sprains, and causes of pain, as well as restrictions in daily living and sports. The degree of disability experienced by the patient depends upon the degree of instability and the physical demands. Many tests for ankle instability are strongly dependent on patient cooperation. If positive, however, they can be highly specific.

- The examiner should check the range of motion of the ankle joint with a stretched and a bent knee to rule out a shortening of the gastrocnemius or soleus muscle (or both). Restricted dorsiflexion with a stretched knee joint that is not found with a flexed knee is specific for a shortening of the gastrocnemius muscle (Silfverskiöld test).
- The inversion test is used to assess for a ruptured CFL.
- Medial ankle stability is checked in a plantarflexed position of the ankle to avoid a locking of the talus in the joint, which can mimic ligamentous stability. If positive, it is highly specific for a ruptured deltoid ligament.
- Insufficiency of the fibulocalcaneus ligament often affects the stability of the subtalar joint. The stability is checked in dorsiflexion of the ankle to lock the talus in the upper ankle joint. If positive, it is highly specific for a ruptured CFL in combination with subtalar instability.
- Effusion can be palpated ventral, but smaller amounts of fluid are difficult to detect.
- The ankle drawer test strains the ATFL and is highly specific for rupture of this ligament.

**Imaging and Other Diagnostic Studies**

- Plain radiographs should be obtained to evaluate potential bony pathology.
- Stress radiographs: The AP view shows the lateral opening of the joint. An anterior talar shift can be seen on the lateral stress view (Fig 3).
- MRI gives valuable information on the lateral ligaments and other pathology. In chronic instability scarring is often found. However, it is impossible to judge functional stability in an MRI. Frequent additional pathologies visible on MRI are tears of the peroneal tendons, osteochondral lesions, and bone edema.

**Differential Diagnosis**

- Articular injury (chondral or osteochondral fractures)
- Nerve injuries (sural, superficial peroneal, posterior tibial)
- Tendon injury (peroneal tendon tear or dislocation, tibialis posterior)
- Other ligamentous injuries (syndesmosis, subtalar, bifurcate, calcaneocuboid)
- Impingement (anterior osteophyte, anteroinferior tibiofibular ligament, scars)
- Unrelated pathology, masked by routine sprain (undetected rheumatoid condition, diabetic neuroarthropathy, tumor)

**Nonoperative Management**

The goals of nonoperative treatment are improving proprioception and strength. This can be achieved by physiotherapy and exercises.

- Shoe modifications include a lateral wedge or a flare.
- Means of external fixation are orthoses, braces, or taping. However, these methods are limited.
- Tape loses 30% of its stability after 200 steps. Skin problems are reported in up to 28%.
- Within the group of orthoses, semirigid, warped types provide the highest degree of stability.
- For many patients with symptomatic instability or pain, nonsurgical measures are not acceptable as a long-term solution. Usually these patients require a lateral ligament repair.

**Surgical Management**

In patients with no previous surgery and good tissue quality, the Broström procedure is a good option, reinserting the original ligaments in place. Especially with modern anchor techniques, this procedure has regained a great deal of popularity.
Broström showed in his work that even after a longer period of chronic instability, a reconstruction of the original ligaments is possible, providing sufficient stability and function of the ankle joint.4

- However, most patients with a history of recurrent inversion trauma do not have adequate tissue quality to perform a Broström procedure.5,10,16
- Insufficient local tissue can be augmented or replaced by a tendon graft.
- There are different options of tendon grafts, each with certain advantages and disadvantages.
  - Tenodesis: The major disadvantage of tenodesis procedures (eg, Evans or Watson-Jones) is that they often end up in persistent pain14,15 in combination with an increasing lack of stability over time.12,17
  - Autologous or homologous semitendinosus tendon or gracilis tendon can be used as graft. Although in general tolerated well, there is some risk of donor site morbidity after harvesting those tendons.1 If a homologous graft is used, there is a small risk of infection.
  - A local tendon that can easily be harvested with a minimum of donor site morbidity is the plantaris longus tendon.7

Preoperative Planning
- In about 3% of the patients, no plantaris longus tendon can be found or it is not long enough for transplantation. A strategy has to be discussed with the patient as to how to proceed in this case. An option is to change to a technique using another transplant (eg, the gracilis or semitendinosus tendon).

Examinations performed under anesthesia include range of motion of the ankle joint and the ankle stress tests to confirm the previous results, without an active stabilization of the ankle joint by the patient.

Additional intra-articular pathology is a common finding. In most cases, it is advisable to do an arthroscopy of the ankle joint before the final reconstruction.9

Positioning
- The patient is positioned supine with a sand sack under the injured side.
- The procedure is performed with a tourniquet (FIG 4).

Approach
- The plantaris longus tendon is harvested using a medial cut between the soleus and gastrocnemius muscle (FIG 5A).
- The procedure is performed with a standard lateral approach, straight, from the fibula directed to the base of the fifth metatarsal (FIG 5B).

FIG 4 • The patient is positioned supine with a sand sack under the injured side.

FIG 5 • A. Medial approach to harvest the plantaris longus tendon. B. Lateral approach with a 6- to 8-cm cut from the fibula toward the base of the fifth metatarsal.
HARVESTING OF PLANTARIS LONGUS

- Make a 3-cm cut at the medial aspect of the calf where the muscle has its highest volume (TECH FIG 1).
- When the muscular fascia is split, the soleus and the gastrocnemius can be bluntly separated.
- The tendon structure found medially between the two muscles is the plantaris longus tendon, which can easily be harvested with a tendon stripper. The plantaris longus tendon often is much easier to identify at this location than at the medial aspect of the calcaneus.
- If it is not possible to mobilize the plantaris longus tendon distally with the tendon stripper, the tendon can be cut through a small longitudinal incision (about 1 cm).
- Free the tendon from any muscular or fatty tissue.
- Reinforce one end of the tendon with a 0 nonabsorbable suture.
- Store the tendon in a moist compress.

TECH FIG 1 • Harvesting of the plantaris longus tendon. A. Medial incision between the soleus and gastrocnemius muscle. The fascia is directly under the fatty tissue. B. After a longitudinal incision of the fascia, the plantaris longus tendon is found right between the soleus and gastrocnemius muscle. C. The tendon is mobilized with a tendon stripper. D. The end of the plantaris longus is reinforced with a 0 nonabsorbable suture and stored in a moist compress.

ANATOMIC RECONSTRUCTION OF THE LATERAL LIGAMENTS WITH THE PLANTARIS LONGUS TENDON

- Expose the lateral ligaments and the distal fibula via a lateral approach.
- The tissue of the sinus tarsi can be reamed, especially if there is any evidence of inflammation.
- Inspect the quality of ligaments and local tissue.
- Drill two holes at the ventral aspect of the fibula with a diameter of 3.2 mm and a distance of 7 and 13 mm from the tip of the fibula (TECH FIG 2).
- Drill a third hole on the lateral side.
- With a small Weber forceps, connect the ventral holes and flatten the sharp edges surrounding them.
- Drill another two holes at the lateral aspect of the neck of the talus with a diameter of 3.2 mm and a distance of about 8 mm. The holes are located just at the border of the cartilage. In quite a few cases, remnants of the original ligaments can be found at this location.
- Again, create a canal with the Weber forceps.
- Retract the peroneal tendons, and have the assistant position the hindfoot in maximum pronation. Drill two holes and connect them, 13 mm from the joint line of the subtalar joint, similar to the technique mentioned before.
TECH FIG 2 • Anatomic reconstruction with the plantaris longus tendon. A. Drilling a hole at the anatomic insertion of the anterior talofibular ligament. B. Creating a canal between the drill holes with a Weber forceps. C. Routing the tendon through the drill holes. D. Any spare tissue of the tendon can be used for a further reinforcement. E–O. Routing the tendon through the drill holes. (continued)
Indications
- A complete history and physical examination should be performed.
- Care must be taken to address associated pathology.
- Graft augmentation is always indicated when the local tissue is insufficient.

Graft management
- A strategy has to be discussed with the patient if the plantaris longus tendon cannot be identified or is not suitable for transplantation.
- Extreme care should be taken when harvesting and preparing grafts.
- Graft should be secured at all times and handled carefully.

Fixation problems
- If the tendon does not go through the holes, try again to smooth the edges with a Weber forceps.
- If the plantaris longus tendon is too short for the whole routing, use a single layer, where the local tissue is best.
- Fracture of the bony bridges between the drill holes can be managed with anchors or with a transosseous suture of the graft.

PEARLS AND PITFALLS

POSTOPERATIVE CARE
- All patients are kept in a walking boot or walking cast for 2 weeks, and weight bearing is limited to 10 kg. After 2 weeks they get an ankle brace for another 4 weeks with full weight bearing in normal shoes. The ankle brace should be used day and night. In addition, physiotherapy with active stabilization is started in the third week. Cycling is normally possible after 4 to 6 weeks, running after 8 to 10 weeks. The patient should avoid contact sports, including soccer, for 3 to 5 months.

OUTCOMES
- Hintermann and Renggli\(^8\) published a series on this technique and found 78% excellent, 18% good, and 4% satisfying results in the AOFAS hindfoot score. Those good results match our experience.
- Especially athletic patients benefit from anatomic repair of the ligaments, which seems to produce more reliable and much better results than tenodesis.
COMPICATIONS
- Intraoperative graft mishandling
- Graft failure or rupture
- Fracture of the fibula
- Deep venous thrombosis
- Infection
- Loss of motion

REFERENCES
DEFINITION

- Deltoid ligament deficiency is present when both the deep and superficial components of the medial collateral ligament complex of the ankle are ruptured or are insufficient.
- Deltoid ligament deficiency may result from degenerative (eg, late-stage adult acquired flatfoot deformity), postoperative, 6–8 or traumatic or athletic 4 causes.

ANATOMY

- The deltoid ligament complex is a multiunit structure that provides support and restraint for the tibiotalar joint, subtalar joint, spring ligament, and talonavicular joint.
- There is wide agreement that the deltoid ligament complex is made up of both deep and superficial components.
- The deep portion of the complex originates from the intercollicular groove and posterior colliculus of the medial malleolus and inserts on the medial face of the talar body near the center of rotation of the tibiotalar joint. These short and stout fibers are intra-articular but extrasynovial. It is made up of anterior and posterior fascicles.
- There has not been agreement over the superficial components of the complex. In one of the more detailed anatomic studies Pankovich and Shivaram 5 described the superficial layer as being made up of the tibionavicular, tibiocalcaneal, and tibiotalar ligaments. These fibers represent a triangular array originating on the distal medial malleolus and extending in a fan shape to their respective insertions. The relative contribution of these components to both ankle and foot biomechanics is still a topic of investigation.

PATHOGENESIS

- The most common cause of deltoid ligament disruption is supination–external rotation ankle (SER) fractures. The most severe form of these fractures has either a medial malleolus fracture or a deltoid ligament rupture, in conjunction with a lateral malleolus fracture. The variant with an intact medial malleolus and disrupted medial collateral ligaments is termed SER IV-deltoid. This latter form is the most common form of deltoid ligament disruption.
- It has been very well established that deltoid reconstruction is not indicated for disruptions that occur in conjunction with ankle fractures. Reduction and fixation of the fracture component with re-establishment of the mortise morphology leads to healing of the deltoid ligament in the vast majority of those with these combined injuries. 9
- A smaller proportion of patients with deltoid ligament insufficiency will have developed this as a component of stage IV adult acquired flatfoot disorder (AAFD). 2
- Deltoid ligament insufficiency without concomitant ankle fractures resulting from the acute injury has been described but will not be discussed here. This chapter will concentrate on deltoid ligament insufficiency arising from degenerative causes.

NATURAL HISTORY

- As the posterior tibial tendon becomes deficient, the ability to bring the hindfoot into varus actively is lost.
- As the mechanical axis of the leg is shifted medially (relative to the foot) and the hindfoot deformity becomes more severe and eventually stiff, tension is progressively increased on the soft tissues of the medial ankle. The medial collateral ligament complex becomes unable to resist the loads placed upon it, with eventual insufficiency and lengthening. 7, 8
- Progression to stage IV AAFD occurs when the deltoid ligament becomes incompetent and the valgus force from the pre-existing hindfoot deformity causes the talus to tilt within the mortise.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Aspects of the history and physical examination of stage IV AAFD will be similar to those found in the earlier stages of this AAFD.
- There will be hindfoot valgus.
- Because of the chronic nature of posterior tibial tendon involvement, strength will be greatly diminished and likely absent because of rupture. The patient will neither be able to resist hindfoot eversion nor actively bring the forefoot across midline.
- Because of the decreased working length of the triceps surae resulting from chronic hindfoot valgus, there will be contracture of these muscles. A fixed hindfoot deformity may give a falsely optimistic impression of tibiotalar dorsiflexion. Re-establishment of ankle and hindfoot alignment without an appropriate lengthening of the heel cord will create or exacerbate an equinus deformity.
- There may be significant forefoot supination.
- Lateral pain may represent sinus tarsi or subfibular impingement, lateral ankle joint arthritis, or in severe cases distal fibular stress fracture.
- Pain in the sinus tarsi is frequently unrecognized or underestimated before palpation by the clinician.
- Callosity and pain below the talar head may be present if substantial dorsolateral peritalar subluxation has caused a prominence in the medial plantar midfoot.
- It is essential to determine whether the tibiotalar valgus deformity that is a hallmark of stage IV AAFD is rigid or reducible. This is further explained under surgical management.
- Clinical determination of the presence of valgus tibiotalar deformity is greatly enhanced with radiologic examination.
- The integrity of the lateral collateral ligament complex needs to be determined. A severe valgus deformity may lead to erosion and incompetence of these structures.
- The surgeon must also evaluate for the presence of ipsilateral knee valgus. If this is significant, consideration should be given to correcting the proximal deformity before the foot and
ankle surgery. Correction of the leg–ankle–foot axis without attention to knee deformity may not adequately relieve valgus stress through the reconstructed lower limb and result in recurrence of deformity.

- Methods for examining the deltoid ligament include:
  - Palpating the area inferior to the medial malleolus. Tenderness may represent incipient or recent deltoid rupture and may only be present early in stage IV disease.
  - Joint line palpation. The presence of valgus tilt indicates insufficiency of the deltoid ligament.
  - Weight-bearing AP ankle radiographs. Valgus tilt greater than 4 degrees indicates deltoid ligament insufficiency.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- The preferred radiologic views include the three-view weight-bearing series. The AP standing view will provide the most information. Patients with deltoid ligament insufficiency will demonstrate tibiotalar valgus tilting (FIG 1).
- Cross-sectional imaging is required only when plans are made for performing reconstruction using native peroneus longus tendon (discussed later). In this case MRI is used to confirm the integrity of the peroneus brevis before the longus is harvested.
- Selective intra-articular blocks often help the clinician localize the exact source of pain.

**DIFFERENTIAL DIAGNOSIS**

- Stage II or III AAFD
- Medial malleolus fracture nonunion
- Tibiotalar arthritis (with eccentric lateral joint erosion)
- Osteonecrosis of the talus with lateral collapse
- Distal tibial supramalleolar valgus malalignment (resulting from distal tibiofibular fracture or pilon fracture)
- Valgus malunion of pronation abduction-type ankle fracture with lateral plafond impaction or comminution

**NONOPERATIVE MANAGEMENT**

- In contrast to acute deltoid deficiency presenting in conjunction with an ankle fracture, we believe that nonoperative care has a very limited place in patients with chronic deltoid ligament insufficiency resulting from degenerative causes (eg, stage IV AAFD). All but patients with medical comorbidities contraindicating surgery should undergo surgical reconstruction.
- Conservative therapy may also be needed to relieve pain and temporize deformity while related orthopaedic conditions are corrected.
- Although halting the progression of the disease may be possible with conservative therapy, the deformities of stage IV cannot be corrected with bracing alone.

**SURGICAL MANAGEMENT**

- Healing of a chronically insufficient deltoid ligament to a functional structure does not occur in AAFD. Reefing and other surgical techniques attempting to incorporate this diseased tissue into the repair do not produce reliable results. Allograft or autograft reconstructions of the deltoid ligament give the best chances for success.
- Once a diagnosis of stage IV AAFD is made, an operative plan to correct all components of the deformity is needed.
- Evaluation of the ability to passively correct the tibiotalar deformity is central to whether the deltoid ligament may be reconstructed for salvage of the ankle joint.
- Tibiotalar valgus deformity that can be corrected passively may benefit from deltoid reconstruction in conjunction with bony and tendon work. Rigid tibiotalar deformity of stage IV AAFD should be reconstructed with tibiotalocalcaneal or pantalar fusion.
- It is essential to correct all components of the foot deformity along with deltoid reconstruction so that the forces that resulted in the native deltoid ligament insufficiency are neutralized and do not cause failure of the reconstructed ligament.
- If lateral collateral ligament insufficiency is found on examination, the surgical plan should include reconstruction of these structures.

**Preoperative Planning**

- Imaging studies are reviewed.
- Examination under anesthesia (EUA) should be accomplished before positioning the patient. Intraoperative fluoroscopy may be very useful during the EUA.
- It is also important to re-evaluate the lateral collateral ligaments during the EUA.
- All foot reconstructive procedures needed to restore plantigrade alignment should be done at the same surgical sitting if possible. These procedures should be done immediately before deltoid ligament reconstruction.

**Positioning**

- The patient should be positioned supine on the operating table.
- Retrograde application of an Esmarch bandage followed by inflation of an upper thigh tourniquet may be used to create a relatively bloodless field.
- Access to the medial ankle may be improved by placing a soft support under the contralateral hip.
The surgeon should ensure that the lower extremity is prepared and draped to a level above the knee so that limb–foot alignment may be evaluated intraoperatively.

**Approach**

- The approach for the minimally invasive deltoid ligament reconstruction (MIDLR) requires a longitudinal incision from the tip of the medial malleolus to just inferior to the prominence of the sustentaculum tali. This incision may need to be carried through incompetent fibers of the superficial deltoid ligament (FIG 2).
- The approach for the peroneal grafting method uses a straight longitudinal incision over the peroneal tendons to harvest the peroneus longus tendon and then a medial incision through which the tendon is brought before threading it through and securing it to the tibia. The patient should be initially positioned with a bump under the ipsilateral hip, which may be removed when increased access to the medial ankle is required.

**MINIMALLY INVASIVE DELTOID LIGAMENT RECONSTRUCTION**

- This technique\(^1\)\(^2\) reconstructs components of both the superficial and deep layers of the deltoid ligament without sacrificing any host tissue for graft.

**Forked Allograft Preparation**

- Cadaveric allograft from the posterior tibial tendon or the peroneal tendon provides a graft of good size. Larger grafts (eg, Achilles tendon) may be used but should be cut to appropriate thickness. Do not use grafts smaller than the posterior tibial tendon or peroneals.
- The graft should be about 20 cm in length and 6 to 7 mm in diameter. Split one end longitudinally, leaving about 5 cm of the opposite end unsplit.
- Place Krackow stitches of no. 00 nonabsorbable woven suture in all three limbs of the tendon (TECH FIG 1).
- After preparation, wrap the graft in moistened gauze and set it aside.

**Tibial Limb Placement**

- Above the medial malleolus, in the midcoronal plane, choose a level about 1 cm above the plafond at which the tibial limb of the graft will be anchored. This is approximated well by the level of the distal tibial physeal scar. Intraoperative fluoroscopy is very helpful in locating a proper site. The saphenous vein and nerve should be anterior to the entry site chosen.
- At the level for insertion, make a 1-cm longitudinal incision down to medial tibial cortex. Advance a guidewire from medial to lateral parallel to the plafond (TECH FIG 2). Make a 6.0-mm blind tunnel over the guidewire for a distance of 25 mm. Remove the guidewire.
- Secure the tibial limb (unsplit end) of the forked graft in the blind tibial tunnel using a 6.25-mm soft tissue interference screw (TECH FIG 3). Use manual testing to ensure that the graft is adequately anchored in the tunnel.

**Talar Limb Placement**

- The path of the tunnel through the talus starts at the medial center of tibiotalar rotation. This is most easily approximated by drilling the insertion point for the native deep deltoid ligament. The lateral exit of the tunnel is located at the lateral junction of the talar dome and neck. This lateral exit point is located by palpation. If this junction cannot be palpated, a small incision may need to be made to locate the lateral neck body junction. Advance a guidewire for a cannulated 5.0-mm drill along this axis. Confirm the position of the guidewire with AP and lateral fluoroscopic views.
- Drill a 5.0-mm tunnel over the guidewire. Pass one end of the sutured tendon through the tunnel from medial to lateral using a suture passer. Place appropriate tension on the graft and place a 5.0-mm soft tissue interference screw in the medial aspect of the tunnel to secure the graft. Advance the interference screw so that it is countersunk 1 to 2 mm into the tunnel.
Calcanéal Limb Placement

- Using palpation, locate the medial border of the sustentaculum tali. Once it is found, carefully dissect the posterior tibial tendon sheath away from the bone and retract it inferiorly. Insert the guidewire for the cannulated drill along an axis from the midportion of the sustentaculum tali to a point about 1 cm superior to the peroneal tubercle on the lateral side of the calcaneus (TECH FIG 4A). Placing the guidewire in this location allows for centralization in the sustentaculum and minimizes the chances of breaching the subtalar joint. Check the position of the guidewire using fluoroscopy.
- Create a 5.0-mm tunnel over this guidewire.
- Pass the free end of the remaining limb of the tendon graft through the sustentacular tunnel and out the skin overlying the lateral calcaneus. A small slit may need to be made to allow the graft to be pulled fully through. Perform tensioning and tibiotalar joint position manually and check it under fluoroscopy.
- When appropriate tension is achieved, insert a 5.0-mm interference screw from medial to lateral into the sustentacular tunnel.
- The appearance of the final construct in situ is illustrated in TECH FIG 4B. An illustration of the position of the graft after insertion and fixation is shown in TECH FIG 4C.
- Close the wounds in a layered fashion.
Chapter 103  DELTOID LIGAMENT RECONSTRUCTION

TECH FIG 4 • Calcaneal limb placement. A. Starting point for the calcaneal limb with guidewire advanced so as to avoid the subtalar joint and exit out the lateral calcaneal cortex. B. Completed minimally invasive deltoid ligament reconstruction in situ from the medial aspect. C. Completed minimally invasive deltoid ligament reconstruction from the medial aspect and from a posteroanterior view.

PERONEUS LONGUS GRAFT TENDON HARVESTING

- Harvest the peroneus longus tendon through a lateral incision that extends from the fourth metatarsal base to about midway up the calf.³
- Tenodese the proximal stump of the transected peroneus longus tendon to the peroneus brevis.
- After securing a Krackow locking suture to the free end of the peroneus longus tendon, wrap it in a piece of moist gauze.

Talar Tunnel Construction

- Make a medial incision centered over the medial malleolus, extending distally over the fibers of the superficial deltoid.
- Divide the fibers of the attenuated deltoid ligament, exposing the medial aspect of the talus.
- Pass an intraosseous guidewire from the lateral talar neck-body junction to the estimated center of rotation on the medial aspect of the talus inferior to the tip of the medial malleolus.
- Verify guidewire position fluoroscopically and clinically by dorsiflexing and plantarflexing the ankle to determine if the center of rotation has been localized.
- Create a tunnel using a cannulated reamer about 4 to 5 mm in diameter.

Tibial Tunnel Construction

- Create a second bony tunnel from the tip of the medial malleolus to a point in the lateral distal tibia. The exit point is about 5 to 6 cm proximal to the tibial plafond and anterior to the fibula. We recommend saving the shavings from the reamer to be used later as bone graft.

Graft Passage and Fixation

- Pass the tendon through the tibial tunnel from distal-medial to proximal-lateral.
- Tension the tendon first at the medial talar tunnel and then at the lateral tibial exit site, with correction of valgus talar tilt.
- Secure the tendon to the lateral tibia under maximal tension with a soft tissue washer or staple. Pack bone graft obtained from reaming in the bony tunnels. A schematic of the final construct is depicted in TECH FIG 5.
- Close the wounds.
POSTOPERATIVE CARE
- In the immediate period after tibiotalar joint-sparing reconstruction of stage IV posterior tibial tendon rupture, a plaster splint is applied in neutral position. Physiotherapy starts after the incisions have healed, usually about 2 weeks postoperatively. Therapy consists of passive and active mobilization of the ankle joint as well as intrinsic muscle exercises. Weight bearing is started progressively but is not full until 12 weeks postoperatively. Gait training is instituted as needed after weight bearing is commenced.

OUTCOMES
- There are no long-term results for these methods because both were recently developed. Studies on outcomes are made difficult by the small number of patients who present with stage IV AAFD. Ongoing studies are evaluating the ability to maintain the correction and stability obtained with these methods.
- Two-year clinical results for the forked graft method are just becoming available at the time of the writing of this chapter. Initial short-term results are promising, with maintenance of tibiotalar joint motion and stability in those who have undergone the procedure.
- Short-term follow-up data are available for the peroneus longus graft method. In the five patients evaluated after undergoing this procedure, four had tibiotalar valgus correction to 4 degrees or less that was maintained 2 years after the procedure.
COMPLICATIONS

- Breaching tibiotalar joint with misplaced tibial or talar tunnel
- Breaching subtalar joint with misplaced calcaneal tunnel (forked graft method)
- Damage to superficial peroneal nerve
- Damage to deep peroneal nerve (peroneal graft method)
- Damage to the sural nerve on calcaneal limb pull-through (forked graft method)
- Infection
- Graft failure or rupture

REFERENCES

DEFINITION

- Pronation injuries of the ankle joint complex may result in a partial or complete disruption of the superficial anterior bundles of the deltoid ligament.
- Chronic medial ankle instability may cause a secondary posterior tibial dysfunction over time, as the tendon may become elongated, ruptured, or both.
- Medial ankle instability may also be the result of a posterior tibial dysfunction with chronic overload of the deltoid ligaments and consecutive step-by-step disruption.
- Medial ankle instability must be suspected if the patient complains of “giving way,” especially medially, when walking on even ground, downhill, or downstairs, pain at the anteromedial aspect of the ankle, and sometimes pain on the lateral ankle, especially during dorsiflexion of the foot.

ANATOMY

- The deltoid ligament is a multibanded complex with superficial and deep components.
- It may be wise to differentiate the superficial and deep portions of the deltoid complex with respect to the joints they are spanning. The superficial ligaments cross two (the ankle and the subtalar joints) and the deep ligaments cross one joint (only the ankle joint), although differentiation is not always absolutely clear.10
- The three superficial and more anterior bands are the tibionavicular, tibiospring, and tibiocalcaneal ligaments; the three deep bands are the anterior, intermediate, and posterior tibiotalar ligaments (Fig 1).1
- As the tibioligamentous portion of the superficial deltoid has a broad insertion on the “spring ligament,” this ligament complex may interplay with the deltoid ligament in the stabilization of the medial ankle joint, and thus functionally not be separated from it (Fig 1).3

PATHOGENESIS

- Acute injuries to the medial ankle ligaments can occur during running downstairs, landing on an uneven surface, and dancing while the body is simultaneously rotated in the opposite direction. A key feature of the history is whether the patient has sustained a pronation (eversion) trauma—for instance, an outward rotation of the foot during simultaneous inward rotation of the tibia.
- Complete deltoid ligament ruptures are sometimes seen in association with lateral malleolar fractures, or in specific bimalleolar fractures.
- Chronic deltoid ligament insufficiency can be seen in a number of conditions, including posterior tibial tendon disorder, traumatic and sports-related deltoid disruptions, as well as valgus talar tilting in patients with previous triple arthrodesis or total ankle arthroplasty.

NATURAL HISTORY

- There is evidence that the medial ankle ligaments are more often injured than generally believed.4,5,7,8
- Several structures contribute to the stabilization of the medial ankle, and in the case of injury they are not involved in a uniform way. Medial ankle instability is thus not a single entity, and this has most important consequences for treatment.
- The findings of an exploratory, prospective study on 51 patients (53 ankles) have supported our belief that medial ankle instability without posterior tibial tendon dysfunction does exist as an entity.7 It is, however, not clear yet whether, or to what extent, such a medial ankle instability may cause a secondary posterior tibial dysfunction over time, as the tendon may become elongated, ruptured, or both.
- What is clear from the literature is that a coexisting pronation deformity of the foot will lead to further deterioration over time, as the medial ankle ligaments are chronically overstretched.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of medial ankle instability is made on the basis of the history and the results of physical examination, including special maneuvers, and plain roentgenography.
- Medial instability is suspected if the patient complains of “giving way,” especially medially, when walking on even ground, downhill, or downstairs, pain at the anteromedial aspect of the ankle, and sometimes pain on the lateral ankle, especially during dorsiflexion of the foot.
- A history of chronic instability, manifested by recurrent injuries with pain, tenderness, and sometimes bruising over the medial and lateral ligaments, is considered to indicate combined medial and lateral instability that is thought to result in rotational instability of the talus in the ankle mortise.
- Acute injuries may present with tenderness and hematoma at the side of the deltoid ligament.

FIG 1 • Anatomic situs of medial ankle. The superficial and deep deltoid consists of three distinct bundles each.
Physical examination methods for chronic medial ankle instability should include:
- Standing test. Inspect for malalignment, deformity, asymmetry, and swelling. Asymmetric planus and pronation deformity of the affected foot may indicate medial ankle instability: distinct, moderate, important.
- Palpation of anteromedial ankle. Pain in the medial gutter is typically provoked by palpation of the anterior border of the medial malleolus. It is the result of underlying synovitis due to chronic shifting of the talus within the ankle mortise.
- Anterior drawer test is a highly sensitive test for medial ankle instability.

A complete examination of the hindfoot should also include evaluating associated injuries and ruling out other possible causes. These include, among others:
- Fracture of medial malleolus: After an acute injury, radiographic analysis must be performed routinely to exclude a fracture of the medial malleolus (e.g., bony avulsion of the deltoid ligament) or fibula fracture with or without syndesmotic disruption.
- Loss of posterior tibial function after partial or complete rupture: The patient cannot correct the deformity while standing or create supination power to the foot.
- Talonavicular coalition: The subtalar joint is not mobile; so there is no varusization of the heel while going into the tiptoe position.
- Neurologic disorder: There is partial or complete palsy of one or more muscles due to deficient neurologic control.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Acute injury: Plain radiographs, including AP and lateral views, should be obtained to rule out bony avulsion fractures or associated injuries.
- Chronic injury: Plain weight-bearing radiographs, including AP views of the foot and ankle and a lateral view of the foot, should be obtained to rule out old bony avulsion fractures, secondary deformity of the foot (e.g., valgus malalignment of the heel, dislocation at the talonavicular joint), and tibiotalar alignment (e.g., medial gapping of the joint due to incompetence of the deltoid ligament) (FIG 2).

**DIFFERENTIAL DIAGNOSIS**
- Bony avulsion fracture of the medial malleolus (with or without fracture of the fibula or syndesmotic disruption)
- Fixed flatfoot deformity (e.g., acquired flatfoot deformity in adults after posterior tibial dysfunction)
- Osteochondral injury
- Talocalcaneal coalition

**NONOPERATIVE MANAGEMENT**
- Although nonoperative management is controversial, patients with less instability, particularly those who have less of a “giving-way” feeling, and those who are less involved with high-level pronation sports activities, may be treated nonoperatively.
- Nonoperative treatment consists of three components:
  - Medial foot arch supports
  - Physiotherapy for strengthening the invertor muscles
  - A neuromuscular rehabilitation program

**SURGICAL MANAGEMENT**

**Preoperative Planning**
- All imaging studies are reviewed.
- Plain films should be reviewed for fractures, cartilage lesions, hindfoot and midfoot malalignment, and the presence of any hardware (from previous procedures) or foreign bodies.
- Associated fractures, cartilage lesions, foot malalignment, and tendon disruption should be addressed concurrently.
- Examination under anesthesia should be performed to compare with the contralateral ankle.

**Positioning**
- The patient is in the supine position with the feet at the edge of the table.
- A commercially available knee holder is used to support the distal femur and to place the foot into a hanging position (FIG 4).
- This allows the surgeon to move the foot freely while arthroscopy is done before open reconstruction.
- After the arthroscopy, the knee holder is removed, leaving the foot on the table.
Approach
- An anteromedial approach is used for ankle arthroscopy.  
- A gently curved incision of 3 to 5 cm is made, starting 1 cm cranially of the tip of the medial malleolus and running toward the medial aspect of the navicular bone.

ANKLE ARTHROSCOPY
- Arthroscopy is done to visualize the internal structures and to assess medial and lateral ankle stability.  
- After visual evaluation of the ligaments, test lateral and medial ligament stability by applying gentle varus, valgus, and anterior pull stress to the ankle joint under arthroscopic control.  
- Ligament lesions are graded as distended if the ligament is thinned or elongated, and as ruptured if continuity is lost. Because most ligament tears are located on the proximal insertion, this is usually best seen by a completely free insertion area of the ligament on the malleoli (TECH FIG 1).

- As the foot is everted and pronated, the deltoid ligament is considered incompetent when it is tensioned, but obviously no strong medial buttress is created with this maneuver (TECH FIG 2). An excessive lifting away of the talus from the medial malleolus by pulling the foot anteriorly is also considered an indicator of stretching of this ligament.

- If there is additional instability of the lateral ankle ligaments, as found on the clinical examination and confirmed by arthroscopy, a lateral approach to the ankle is also performed to explore the anterior talofibular and calcaneofibular ligaments.

- Lateral instability is considered to be present when talar tilting occurs by supination stress of the foot.
- As evaluated for both the medial and lateral side, the ankle joint is graded as stable when there is some translocation of the talus, but not enough to open the tibiotalar joint by more than 2 mm (as measured by the 2-mm hook) and not enough to introduce the 5-mm arthroscope into the tibiotalar space; as moderately unstable when the talus moves to some extent out of the ankle mortise, allowing introduction of the 5-mm arthroscope into the tibiotalar space, but not enough to open the tibiotalar joint by more than 5 mm; and as severely unstable when the talus moves easily out of the ankle mortise, Typically allowing free insight into the posterior aspect of the ankle joint without significant pulling stress on the heel.  

TECH FIG 1 • Avulsion of anterior superficial layers from medial malleolus. Arthroscopy typically reveals a completely free insertion area of the ligament on the medial malleolus.

TECH FIG 2 • Incompetent deltoid ligament. A. As the foot is everted and pronated, the deltoid ligament is considered incompetent when it is tensioned, but obviously no strong medial buttress is created with this maneuver. B. An excessive lifting away of the talus from the medial malleolus by pulling the foot anteriorly is also considered an indicator of stretching of this ligament.
MEDIAL ANKLE LIGAMENT RECONSTRUCTION

- Complete acute rupture: Because the rupture is mostly situated proximally of the deltoid ligament (TECH FIG 3), reattachment to the medial malleolus is achieved by interosseous sutures; a bony anchor can also be used for refixation to the bone.8
- Chronic ruptures of the superficial deltoid ligament are classified as shown in Table 1.7,8
- Chronic rupture of the superficial deltoid ligament (type I lesion): Expose the anterior border of the medial malleolus by making a short longitudinal incision between the tibionavicular and tibiospring ligaments, where there is usually a small fibrous septum without adherent connective fibers between the two ligaments (TECH FIG 4A). After roughening the medial aspect of the medial malleolus, place an anchor (Panalock®) 6 mm above the tip of the malleolus (TECH FIG 4B); this serves for refixation of

**TECH FIG 3** - Acute deltoid rupture. This 28-year-old soccer player sustained a valgus trauma, causing an acute “giving way” of the foot. A. MR imaging reveals complete disruption of the ligament close to its proximal insertion to the medial malleolus. B. Surgical exploration confirms complete disruption of the deltoid ligament, although the posterior tibial tendon remained intact.

Part 8 FOOT AND ANKLE • Section V SPORTS-RELATED PROCEDURES FOR ANKLE AND HINDFOOT

The second superior anchor on the medial malleolus serves for reattachment of the tibionavicular ligament (TECH FIG 5G). Use additional no. 0 resorbable sutures to further stabilize the reconstructed tibionavicular and tibiospring ligaments (TECH FIG 5H,I).

- Chronic rupture of the superficial deltoid ligament (type II lesion): If necessary, débride the tear (TECH FIG 6A). Then place two nonresorbable sutures in the spring ligament (TECH FIG 6B). If the tibionavicular ligament is completely detached from its insertion, place an anchor (Panalock®) at the superior edge of the navicular tuberosity. After tightening the sutures (TECH FIG 6C,D), use additional no. 0 resorbable sutures to further stabilize the reconstructed tibionavicular and spring ligaments.

- Chronic rupture of the deep deltoid ligament: Because this condition usually includes an extended tear of the superficial anterior bundles of the deltoid ligament, any

 TECH FIG 4 • Chronic rupture of the superficial deltoid ligament (type I lesion). A. The rupture is located between the tibionavicular and tibiospring ligaments, where a small fibrous septum without adherent connective fibers between the two ligaments is usually present. B. After roughening the medial aspect of the medial malleolus, an anchor (Panalock®) is placed 6 mm above the tip of the malleolus. C. It serves for refixation of the tibionavicular and tibiospring ligaments to the medial malleolus, and to shorten both ligaments. D. Final reconstruction after some additional no. 0 resorbable sutures. E. Principle of reconstruction.

 TECH FIG 5 • Chronic rupture of the superficial deltoid ligament (type II lesion). A. The superficial deltoid ligament is scarred and incompetent. B. Two anchors (Panalock®) are placed 6 and 9 mm above the tip of the medial malleolus. (continued)
**TECH FIG 5 (continued)**

C. Another anchor (Panalock®) is placed into the tuberosity of the navicular bone.

D. The deep flap is reattached to the medial malleolus using the distal anchor suture.

E. The superficial flap is reattached to the tuberosity of the navicular bone using the anchor suture.

F. A strong and well-tightened ligament reconstruction is thus obtained.

G. The second superior anchor on the medial malleolus serves for reattachment of the tibionavicular ligament.

H. Additional no. 0 resorbable sutures are used to further stabilize the reconstructed tibionavicular and tibiospring ligaments.

I. Principle of reconstruction.

**TECH FIG 6**

Chronic rupture of the superficial deltoid ligament (type III lesion).

A. The distal tear in the spring ligament is exposed and débrided.

B. Two nonresorbable sutures are placed in the spring ligament.

C. The sutures are tightened.

D. Principles of reconstruction.
TECH FIG 7 • Chronic rupture of the deep deltoid ligament. After the posterior tibial tendon has been split into two bundles, both bundles are inserted into a drill hole at the tip of the medial malleolus (arrow). One bundle is conducted through the anterior tunnel at the anterior aspect of the medial malleolus, and the posterior bundle is conducted through the posterior tunnel at the posterior aspect of the medial malleolus.

TECH FIG 8 • Chronic rupture of the deep deltoid ligament. A. Exposure of the posterior tibial tendon reveals a tear. B. Exposure of the deltoid ligament reveals an extended disruption and incompetence of the superficial and deep layers. C. A bone–tendon–bone transplant is fixed by screws distally into the navicular bone and, after tightening, proximally to the posterior aspect of the medial malleolus. D. Multiple nonabsorbable and absorbable sutures are used for further reconstruction of the ligament.

Reconstructive surgery should attempt to address the whole deltoid ligament. The posterior tibial tendon can be used as a graft for augmentation of the reconstructed deltoid ligament by passing it through a drill hole from the tip of the medial malleolus to the medial aspect of the distal tibia (TECH FIG 7). This technique was found to be disappointing, however, as it does not sufficiently reinforce the deep tibiotalar ligaments (Hintermann, unpublished data). Most recently, the use of a bone–tendon–bone transplant has been proposed for reconstruction of the deltoid ligament (TECH FIG 8). In this in vitro study, two limbs were created on a distal transplant; one was fixed to the medial aspect of the talus and the other to the sustentaculum tali. The proximal end was fixed to the distal tibia, the medial malleolus, or the lateral tibia. Less than 2.0 degrees of angulation was found while applying valgus stress of 5 daN for all fixation methods. However, the authors advised against fixation of the proximal limb in the medial malleolus.
LATERAL ANKLE LIGAMENT RECONSTRUCTION

- About 75% of patients with chronic medial ankle instability were found to have an associated avulsion of the anterior talofibular ligament that resulted in a complex rotational instability of the talus within the ankle mortise.7
- If the condition of the anterior talofibular ligament and the calcaneofibular ligament allows an adequate primary repair, these ligaments can be reconstructed by shortening and reinsertion (TECH FIG 9).
- When no substantial ligamentous material is present, augmentation with a free plantaris tendon graft is performed (TECH FIG 10).12

Posterior Tibial Débridement and Reconstruction

- Inspect the posterior tibial tendon meticulously during surgery, especially in the case of a type II or type III lesion of the anterior deltoid ligament.
- If there is degeneration of the tendon, débride the tendon.
- If there is elongation of the tendon, consider shortening the tendon.
- If there is an accessory bone (os tibiale externum), consider reattaching the bone with the tendon insertion; the posterior tibial tendon can also be tightened if the bone is reattached more distally to the navicular bone (TECH FIG 11).9

Lateral Lengthening Calcaneal Osteotomy

- This procedure is considered in the case of a pre-existing valgus and pronation deformity of the foot (eg, when a valgus and pronation deformity is also present on the contralateral, asymptomatic foot) or in the case of a severe attenuation or defect of the tibionavicular, tibiospring, or spring ligaments.
- A calcaneal osteotomy is performed along and parallel to the posterior facet of the subtalar joint, from lateral to medial, preserving the medial cortex intact (TECH FIG 12A–D).6
- As the osteotomy is widened, the pronation deformity of the foot is seen to disappear (TECH FIG 12E).
- Fashion a tricortical graft from the iliac crest to the length required and place it into the osteotomy site (TECH FIG F–H).

TECH FIG 9 • Primary anatomic repair of lateral ankle ligaments. A. Exposure of lateral ligaments and arthrotomy of ankle and subtalar joints that are débrided. The scarred anterior portion of the lateral ligaments is widely disconnected from the anterior border of the fibula. B. The anterior border of the fibula is roughened. C. An anchor or transosseous sutures are used to reattach the avulsed lateral ligaments (eg, the anterior tibiofibular and calcaneofibular ligaments at their common insertion 8 to 10 mm above the tip of lateral malleolus). D. A strong and well-tightened ligament reconstruction is thus obtained.
TECH FIG 11 • Unstable os tibiale externum. A. An unstable accessory bone (os tibiale externum) is found to weaken the pull of posterior tibial tendon. B. The accessory bone is mobilized and 3 to 5 mm of bone is removed on both sides of the pseudarthrosis. C. This allows for reattachment of the accessory bone more distally to the navicular bone, using screws and nonabsorbable sutures.

TECH FIG 10 • Reconstruction of lateral ankle ligaments with a free plantaris tendon graft. A. The remaining scarred ligaments do not allow primary repair of lateral ankle ligaments. B. A free plantaris tendon graft is used for reconstruction of the anterior talofibular and the calcaneofibular ligaments. C. A strong and well-tightened ligament reconstruction is thus obtained.

Double Arthrodesis
- This procedure is considered when the medial ankle instability is so excessive that a valgus tilt of the talus within the mortise is seen on a standard AP view of the ankle while the foot is loaded (Fig 2).11
- Be sure to fully correct the whole deformity (eg, valgus malalignment of the heel, and the peritalar dislocation of talus).
- Expose the talonavicular joint from medially through the same incision (TECH FIG 13A,B).
- Use a distraction spreader (Hintermann spreader) to open the joint; this allows for cartilage removal and debridement (TECH FIG 13C,D).
- Expose the subtalar joint from medially through the same incision.
TECH FIG 12 • Calcaneal lengthening osteotomy. **A.** The neck of the calcaneus is exposed using a lateral incision. **B.** The osteotomy is marked by a cisel to be directed through the sinus tarsi along the anterior border of the posterior facet of the subtalar joint. Two Kirschner wires for the Hintermann retractor are inserted. **C.** Osteotomy is performed using a saw. **D.** The osteotomy is opened using the retractor. **E.** As the osteotomy is widened, the pronation deformity of the foot is seen to disappear. **F.** A tricortical graft from the iliac crest or an allograft is fashioned to the length required and placed into the osteotomy site. **G.** The border of the inserted graft is smoothed. **H.** A regular bony contour on the bottom of the sinus tarsi is thus obtained.
Use the distraction spreader to open the joint; this allows for cartilage removal and débridement (TECH FIG E–G).
Correct the deformity first by reducing the former talonavicular joint, making sure to correct the frontal plane position of the navicular (eg, to achieve full correction of any forefoot supination deformity) (TECH FIG 13H–L).

Stable fixation is achieved by triple screw fixation at the talonavicular and double screw fixation at the subtalar joint (TECH FIG 13M–O).

Wound Closure
- Close the wounds in layers.
- Close the subcutaneous tissue and skin in standard fashion.

**TECH FIG 13** • Double arthrodesis. 
- A. Skin incision just above the posterior tibial tendon; the surgeon should stop proximally at a perpendicular line through the medial malleolus (eg, so as not to damage the deep bundles of the deltoid ligament). 
- B. Incision of skin and dissection of the medial ankle ligaments by sharp incision along the spring ligament. 
- C. The talonavicular joint is exposed first. The Hintermann retractor serves to expose the joint. 
- D. Cartilage is removed and the joint is cleaned to subchondral bone. 
- E. A third Kirschner wire is inserted into the sustentaculum tali of the calcaneus. This allows the surgeon to open the subtalar joint using the Hintermann distractor. 
- F. The cartilage is removed. 
- G. Final inspection shows complete débridement of the subtalar joint, including the sinus tarsi. (continued)
TECH FIG 13  * (continued)  

**H.** The Kirschner wires in the navicular and talar bones are kept in place and serve to reduce the talonavicular joint properly.  

**I.** Frontal view showing the frontal realignment at the talonavicular joint using both Kirschner wires as joysticks.  

**J.** A first guiding Kirschner wire is inserted through the tuberosity of the navicular into the talus. Afterwards, two other guidewires will be used to properly stabilize the talonavicular joint in the frontal plane.  

**K.** After inserting two additional guidewires from the bottom through the subtalar joint, fluoroscopy is used to insert the cannulated screws (QUIX, Newdeal/Integra).  

**L.** The deltoid ligament is reattached to the spring ligament using nonabsorbable sutures. The foot looks properly positioned at the end of surgery. Note the short incision that is used for this procedure. At 2 months, weight-bearing radiographs are obtained.  

**M.** Lateral view.  

**N.** AP view of the ankle.  

**O.** AP view of the foot.
### POSTOPERATIVE CARE

- The foot is protected by a plaster cast for 6 weeks, and full weight bearing is allowed as soon as pain-free loading is possible. In the case of double arthrodesis, initial plaster immobilization for 8 weeks is recommended.
- The rehabilitation program starts after cast removal. It includes passive and active mobilization of the ankle joint, training of the muscular strength, and protection with a walker or stabilizing shoe when walking.
- A walker or stabilizing shoe can be used for 4 to 6 weeks after cast removal, depending on regained muscular balance of the hindfoot.
- We recommend continued use for walks on uneven ground, for high-risk sports activities, and for professional work outside.

### OUTCOMES

- With appropriate surgical technique, success rates for ligament reconstruction of the medial ankle are on the order of 85% to 90% in terms of return to former sports and professional activities.\(^7\)
- As associated malalignment has been addressed more aggressively in the last years, the success rate has further increased.
- The most troubling problem remains a chronic incompetence of the deep deltoid ligament, which results in valgus tilt of the talus while loading the foot. Despite the use of tendon augmentation, most attempts at isolated ligament reconstruction have failed; the main step is probably a double arthrodesis in getting a stable and well-aligned hindfoot. An alternative may be a tibiocalcaneal arthrodesis.

### COMPLICATIONS

- Deficient stability because of inappropriate ligament reconstruction
- Recurrent instability because valgus deformity was not addressed
- Suture granuloma at the anterior margin of the medial malleolus when using nonresorbable sutures and placing the suture knot onto a bony surface
- Deep venous thrombosis
- Infection
- Scarring in the anteromedial ankle causing soft tissue impingement

### REFERENCES

DEFINITION
- The Achilles tendon is the strongest tendon in the body and is the primary plantarflexor of the ankle joint.\textsuperscript{15}
- Sudden stretch of the tendon tissue can result in complete or partial rupture, with an estimated incidence of 18 per 100,000 persons.\textsuperscript{3}
- With complete rupture, the ruptured ends of the tendon may pull apart, leading to a significant plantarflexion weakness and to the creation of a gap that is palpated clinically.
- A common source of confusion is that patients may continue to have active ankle plantarflexion due to the action of other flexors of the ankle.
- As a result, the diagnosis is initially missed in an estimated 20\% to 25\% of cases.\textsuperscript{5}

ANATOMY
- Three calf muscles—the medial, lateral gastrocnemius, and soleus—converge together to form the “triceps surae” or the Achilles tendon (FIG 1).
- The plantaris muscle originates from the lateral femoral condyle and passes obliquely between the gastrocnemius and soleus to reside medial to the Achilles tendon and inserts into it or the calcaneus. In an anatomic study, the plantaris muscle was absent in 7.3\% of specimens.\textsuperscript{15}

- The Achilles tendon courses distally, rotates 90 degrees internally, the soleus contribution being medial to that of the gastrocnemius, and inserts into the middle third of the flat surface of the posterior calcaneal tuberosity.\textsuperscript{10}
- The middle section of the tendon, 2 to 6 cm proximal to its insertion site, is a hypovascular zone.
- This zone is the narrowest in cross-section and corresponds to the most common site of tendon pathology, including paratenonitis, tendinosis, and tendon rupture.\textsuperscript{10}
- The tendon is surrounded by a paratenon that has a single layer of cells with variable structure, not a true tenosynovium.
- Webb et al\textsuperscript{16} documented the highly variable position of the sural nerve in relation to the Achilles tendon.
- As measured from the calcaneal insertion, the sural nerve crossed the tendon from medial to lateral at a mean distance of 9.8 cm, then coursed distally to lie a mean of 18.8 mm lateral (FIG 2).

PATHOGENESIS
- Achilles ruptures are usually caused by noncontact injuries. Common injury mechanisms leading to Achilles rupture are forceful push-off with an extended knee, sudden unexpected ankle dorsiflexion, or violent dorsiflexion of a plantarflexed foot.\textsuperscript{13}
Achilles rupture can occur high, near the muscle-tendon juncture (9%), at the tendon midportion (72%), or at the calcaneal insertion (19%).

Concomitant injuries such as ankle ligament sprains or ankle or tarsal fractures should be ruled out.

NATURAL HISTORY

Most Achilles ruptures do not have any antecedent symptoms.

A study of histologic scores comparing ruptured tendons with unruptured tendons, however, showed that there were significant histopathologic changes in the ruptured group that were not present in the older, asymptomatic, unruptured group. Therefore, tendinosis may play a role, but the extent of this role remains unknown.

Achilles rupture is more common in men. Studies have shown a male/female ratio of up to 12:1.

From an epidemiologic standpoint, middle-aged men with white-collar professions and recreational athletic activity constitute most of the patients.

Other predisposing factors are leg muscle imbalance, training errors, foot pronation, and use of corticosteroids and fluoroquinolones.

The contralateral risk of rupture was estimated at 26% on return to the same level of sports activities.

PATIENT HISTORY AND PHYSICAL FINDINGS

Most ruptures occur during athletic activity. Patients usually describe a sudden painful snap or shooting pain followed by sudden weakness to foot push-off.

Athletes will be unable to bear weight and will report distal leg swelling and stiffness.

Examination for ruptured Achilles tendon can include:

- Palpable gap test. A gap present indicates complete Achilles rupture with separation of the ruptured ends. It is more reliable when done early after rupture. It is 73% sensitive.
- Calf squeeze test (Thompson test). With patient prone, squeeze the calf and observe foot movement. Compare with the contralateral side.

Knee flexion test. With patient prone, patient actively flexes knee. Observe foot position and compare with other.

Active plantarflexion. This is poorly sensitive and unreliable because powerful plantarflexion may still be possible due to the action of other ankle plantarflexors.

IMAGING AND OTHER DIAGNOSTIC STUDIES

AP, lateral, and mortise view plain radiographs of the ankle should be obtained to rule out concomitant fractures or calcific changes of the Achilles tendon.

On a lateral view, the examiner should look for a disruption of the normal triangular fat pad seen anterior to the Achilles tendon (Kager triangle; FIG 3).

Ultrasonography can provide a dynamic study of the tendon structure and accurately measure gapping of the ruptured tendon ends.

The quality of images is highly dependent on the equipment and operator (FIG 4).

MRI is highly sensitive and specific in diagnosing Achilles tendon rupture.

It provides valuable information about tendon degeneration or other associated injuries (FIG 5).

MRI was found to be superior to ultrasound in diagnostic specificity of chronic Achilles tendinopathy.
DIFFERENTIAL DIAGNOSIS
- Rupture of the medial gastrocnemius
- Plantaris tendon rupture
- Baker cyst rupture
- Acute deep venous thrombosis
- Leg or calf contusion
- Tibia distal shaft fracture
- Posterior ankle impingement or symptomatic os trigonum

NONOPERATIVE MANAGEMENT
- Nonoperative treatment usually entails casting the foot in plantarflexion to allow apposition of the tendon ends, followed by casting the foot in neutral. Treatment continues for 12 weeks.
  - In a recent retrospective review, early recognition and initiation of nonoperative management within 48 hours of injury resulted in a successful functional outcome that was comparable to surgical repairs. In a recent retrospective review, early recognition and initiation of nonoperative management within 48 hours of injury resulted in a successful functional outcome that was comparable to surgical repairs.17
  - Nonetheless, nonoperative treatment carries up to threefold increase in the rerupture rate and may result in weakness of push-off secondary to healing of the tendon in a lengthened position.
  - Nonoperative treatment is often reserved for elderly, sedentary patients and also for patients with diabetes, tobacco use, and steroid use who are at high risk for surgical wound healing.4

SURGICAL MANAGEMENT
- Operative repair and early mobilization is considered the treatment of choice for younger patients with active lifestyles. In most patients, it is established that operative repair results in a favorable functional outcome with a significantly lower rerupture rate.
  - Numerous surgical techniques have been described, including open repair, percutaneous repair, limited open repair, and open repair with augmentation.5
    - In a comprehensive review of the recent literature, Wong et al18 concluded that in terms of outcome and the complication rate, the best results could be achieved with open repair and early mobilization.

Preoperative Planning
- Plain radiographs are reviewed and any displaced fractures are treated at the same surgical sitting.
- MRIs are reviewed to evaluate the quality of tendon tissue and the level of rupture and to measure the tendon gap if present.
- Severe tendon degeneration or a large gap may require a larger incision or tendon lengthening or augmentation; the surgeon should take this into account during preoperative patient counseling.

Positioning
- Achilles tendon repair is performed with the patient prone (FIG 6). We prefer to use a Wilson frame and commercially available foam head rest.
  - A thigh tourniquet is used for intraoperative hemostasis. A leg tourniquet is not recommended because it may tether the calf muscles and prevent intraoperative tendon apposition.
  - Some surgeons prefer to drape both legs for intraoperative comparison and accurate restoration of the resting tendon length. The operated leg should be clearly marked.

Approach
- Open Achilles repair is usually performed through a longitudinal medial, midline, or lateral incision.
- Primary end-to-end repair is done with heavy nonabsorbable suture.
- Modified Bunnell, Kessler, Krackow, and triple-bundle techniques have been described.5
  - In a biomechanical study, Jaakkola et al6 showed that the triple-bundle technique (FIG 7) provided the strongest suture repair. They credited its superior strength to the use of multiple strands and to tying the knots away from the repair site. However, the authors expressed concern over the large amount of suture material used and its possible negative effect on the vascularity of the tendon.
  - At our institution, we have designed a modification of the Krackow technique in which the free ends of one suture are
passed peripherally to encircle the transverse limb of the opposite suture (FIG 8).
- We likened this scheme to wrapping a gift box and named it the gift box technique.
- We have performed biomechanical pull-out studies on 13 Achilles cadaveric pairs comparing the gift box technique to the standard Krackow suture and documented more than a twofold increase in suture pull-out strength.\(^\text{12}\)
- We believe that the modification is simple to perform, minimizes suture material use, and preserves the vasculature of the healing tendon.

**INCISION**

- A longitudinal incision over the medial border of the tendon provides excellent exposure and access to the plantaris tendon and avoids the sural nerve (TECH FIG 1).
- Mobilize the thick skin and subcutaneous layer laterally, and take great care to preserve the paratenon.
- Protect the sural nerve and lesser saphenous vein as they course lateral to the paratenon.
- Enter the paratenon through a midline incision (away from the skin incision).
- Limit dissection at the tendon–paratenon plane, especially anterior to the tendon, to preserve the vascular supply of the tendon.

**MODIFIED KRACKOW SUTURE (GIFT BOX) TECHNIQUE**

- Débride the ends of the ruptured tendon in a limited manner.
- Two no. 2 fortified polyester sutures (Herculine, Linvatec) are used.
- Four loop Krackow locking sutures\(^\text{9}\) are passed on the medial side and four on the lateral side, avoiding the middle third of the tendon width.
- Unlike the classic Krackow suture, we pass our transverse limb in the middle of the tendon as we transition from one side to the other (TECH FIG 2).
- Use straight Keith needles to pass the free suture ends across the rupture site into the opposite end of the tendon.
Chapter 105  OPEN ACHILLES TENDON REPAIR

TECH FIG 2 • The transverse limb of the gift box suture is passed through tendon midsubstance. (Copyright Sam Labib.)

TECH FIG 3 • A. The gift box suture completed and tied. Note the tension created on the transverse limb of the suture, which helps tendon apposition. B. Intraoperative photograph of the completed gift box suture. (A, Copyright Sam Labib.)

TECH FIG 4 • Intraoperative photo after closure of the Achilles paratenon.

TRIPLE-BUNDLE SUTURE TECHNIQUE

- Beskin et al popularized an open repair of the Achilles tendon using no. 1 nonabsorbable polyester suture (Ethibond, Ethicon).
- Three rows of sutures are placed, creating six strands of suture that are tied away from the rupture site (Fig 7).

- Sutures should emerge one superficial and one deep to the transverse limb of the opposite Krackow suture (Fig 8).
- Thus, four suture strands are passed across the rupture site.
- Tie the surgical knots away from the rupture site—in other words, proximal and distal to the Krackow suture.
- Excellent apposition is usually achieved as the knots push on the transverse limbs of opposing sutures and the desired tendon length is recreated (TECH FIG 3).
- Use epitendinous running Prolene no. 3-0 suture to oversew the tendon ends together.
- Meticulously repair the paratenon with no. 3-0 braided polyglycolic absorbable suture (Vicryl, Ethicon) (TECH FIG 4).
- This can be facilitated by placing the ankle in maximum plantarflexion to relax the tendon tissue.
- We believe that midline placement of the paratenon incision facilitates its repair and minimizes the chance of skin tethering to the repaired tendon.
- Perform subcuticular skin closure with no. 4-0 monofilament absorbable suture (Monocryl, Ethicon).

PRIMARY REPAIR WITH AUGMENTATION

- Multiple authors have advocated primary augmentation of Achilles repair, with some preferring plantaris tendon, flexor tendon (TECH FIG 5), or artificial tendon implants.13
- A study by Jessing and Hansen7 however, found no evidence that such augmentation was superior to a nonaugmented end-to-end repair.
PEARLS AND PITFALLS

Clinical evaluation
- Diagnosis of complete rupture can be missed due to other active ankle flexors.
- Ultrasonography or MRI may be needed to verify the diagnosis.
- Care is taken to evaluate concomitant bony or tendon injury.

Nonoperative treatment
- Should be initiated early, with cast application in plantarflexion preferably within 48 hours of injury.
- Tendon gapping should be looked for and corrected.
- Strongly considered for patients with poor skin or vascular compromise. Poorly controlled diabetes and tobacco or steroid use are relative contraindications for surgical treatment.

Approach
- Midline incisions may result in a painful scar.
- A lateral incision places the sural nerve at an added risk of injury.
- Poor tissue handling may result in wound slough or dehiscence.

Tendon tension
- Aggressive trimming of tendon ends may result in significant shortening and undue tension on the repair.
- Use the contralateral limb as your guide to appropriate restoration of resting tendon length.

Suture technique
- Avoid strangulating locking suture techniques, which may compromise tendon healing and promote scar formation.
- Paratenon preservation and repair is mandatory for tendon repair and healing.

POSTOPERATIVE CARE
- Early functional mobilization was shown to yield improved tendon healing.
- A posterior splint holding the site in mild plantarflexion is used for 14 days. Labib et al showed no significant difference in tension when the repaired tendon was positioned in 30, 20, and 10 degrees of plantarflexion.
- Wound inspection is done, a non–weight-bearing cast boot is applied with heel lifts, and daily active range of motion is started.
- The patient is kept non–weight-bearing for a total of 6 weeks, but recent evidence suggests that weight bearing can be started before 6 weeks with no added risk of rerupture or gap formation.
- The patient is allowed gradual return to full weight bearing over an additional 6 weeks.
- At 3 months, full weight bearing is permitted, with low-impact activities.
- At 6 months, full activities are permitted as tolerated.

OUTCOMES
- Based on a literature review, there is overwhelming support for open operative repair and early functional mobilization of Achilles tendon rupture in healthy active individuals. On average, a success rate of 85% to 95% is often quoted.

Wong et al conducted an extensive literature review and concluded that the best results with regard to outcome and complication rate could be achieved with open repair and early mobilization.
- Most authors agree that surgical repair provides a significantly lower rerupture rate and better functional outcome, but these advantages should be weighed against the possible risks of wound dehiscence or infection.
- Recent studies showed a significant temporal improvement in surgical outcome coupled with a net decrease in surgical complications.

COMPLICATIONS
- Delayed or missed diagnosis
- Intraoperative devitalization of tendon, leading to wound infection
- Failure to preserve and repair the paratenon, leading to scarring and skin tethering
- Sural nerve injury and neuroma formation
- Wound dehiscence
- Tendon rerupture
- Loss of ankle motion
- Calf weakness
REFERENCES

DEFINITION
- Achilles tendon ruptures usually occur 3 to 4 cm above the calcaneal tuberosity.
- Although most injuries are “complete” ruptures, “partial” injuries have been described.

ANATOMY
- The Achilles tendon is about 9 cm long and 0.9 cm in diameter.
- The proximal part is composed of the gastrocnemius and soleus tendons.
- The distal portion inserts onto the posterior aspect of the tuberosity of the calcaneus.
- The Achilles tendon is surrounded by the paratenon, a delicate envelope that contributes to tendon vascularization.
- There is an area of poor vascularity located between 2.5 cm and 5 cm above the calcaneal tuberosity.

PATHOGENESIS
- Rupture of the Achilles tendon is a common injury among high-level athletes, recreational sports enthusiasts, or even sedentary individuals.
- Rupture of the Achilles tendon usually occurs during forceful dorsiflexion of the ankle.
- Patients often describe hearing or feeling a “pop” in the back of their ankle.
- Intratendinous degeneration can be found histologically.
- Association with cortisone and fluoroquinolone use has been demonstrated.
- This is typically a lesion of middle age, with peak incidence during the third and fourth decades.

NATURAL HISTORY
- There is a great deal of controversy concerning the treatment of an acute rupture of the Achilles tendon.
- Conservative treatment is found to have a higher rate of tendon rerupture and loss of strength because the tendon heals in an elongated position.
- The major factor motivating surgeons to use a nonoperative approach appears to be avoiding the wound complications that occur with an operative repair.
- An increasing number of reports in the literature have tended to favor operative treatment of an acute rupture of the Achilles tendon.
- The exact type of operative procedure and the postoperative regimen remain controversial.1–9 Mini-invasive techniques are associated with a lower complication rate.10–13
- If soft tissue complications are avoided, excellent functional results and full return to previous activity can be expected.

PHYSICAL FINDINGS
- Physical examination reveals moderate swelling about the posterior aspect of the ankle.
- Patients are usually able to walk, although with moderate pain.
- With the patient prone, spontaneous excess dorsiflexion of the involved ankle is noted.
- In most cases a tender defect (“soft spot”) can be palpated in the Achilles tendon between 2.5 and 5 cm proximal to its insertion into the calcaneal tuberosity.
- The Thompson squeeze test is positive.
- Patients have difficulty walking on their toes or rising up on their heels.

IMAGING AND DIAGNOSTIC STUDIES
- History and physical examination are sufficient to confirm the diagnosis.
- Since these injuries occur in a traumatic setting, plain radiographs of the ankle are strongly advised.
- There have been many reports of associated ankle fractures (medial malleolus).14
- Calcaneal (tuberosity) avulsion will appear on the lateral view.
- Ultrasound and MRI are not required for the diagnosis of Achilles tendon rupture but may be of value when the diagnosis is questionable.

DIFFERENTIAL DIAGNOSES
- Ankle sprain
- Ankle fracture
- Tennis leg (gastrocnemius tear)
- Acute paratenonitis
- Calcaneal (tuberosity) avulsion
- Plantaris tendon rupture

NONOPERATIVE MANAGEMENT
- Nonoperative treatment of acute Achilles tendon ruptures involves prolonged immobilization.
- Prolonged immobilization is associated with musculoskeletal changes (atrophy), increased time necessary for rehabilitation, and delayed return to work and preinjury activities.
- In randomized studies the rerupture rate has been found to be much higher in the nonoperative group.
- However, nonoperative treatment avoids surgical complications.
- Nonoperative treatment should be considered in elderly patients with limited functional expectations, patients with significant tobacco or alcohol addictions, patients receiving chronic cortisone treatment, patients with vascular disease, and patients with severe comorbidities such as renal failure.
Indications and Contraindications

- The indication for this technique is an acute (less than 3 weeks) Achilles tendon rupture occurring between 2.0 and 7.0 cm above the tuberosity of the calcaneus.
- Greater than 90 percent of ruptures of the Achilles tendon occur in the area between 2 and 8 cm above the calcaneal tuberosity.15
  - We believe that ruptures occurring more than 8 cm above the tuberosity (muscular ruptures) can be treated nonoperatively, while ruptures occurring less than 2 cm from the tuberosity necessitate fixation directly to bone.
- Contraindications include chronic rupture greater than 3 weeks in duration, previous local surgery, steroid use, open ruptures and lacerations greater than 6 hours in duration, complex open ruptures with soft tissue defects, and ruptures not occurring between 2 and 8 cm above the tuberosity of the calcaneus.

SURGICAL MANAGEMENT

Preoperative Planning

- Plain films should be reviewed for fracture, avulsion, and calcific tendinopathy.
- All imaging studies are reviewed.
- An examination under anesthesia should be performed before positioning the patient to reconfirm the side of injury.

Positioning

- The patient is placed prone on the operating table.
- A tourniquet is applied around the upper thigh.
- Both legs are included in preparation and draping to compare Achilles tendon tension and spontaneous plantarflexion intraoperatively.
- Plastic draping is not used (the technique involves percutaneous steps).
- Patients receive antibiotic prophylaxis.

Instrumentation

- The Achillon (Newdeal, Integra Life Science) was designed by this author and is made of either a rigid polymer or stainless steel (FIG 1).
  - It is designed to guide the passage of the sutures.
  - It is composed of a pair of internal branches connected to a pair of external branches, with each branch having a line of apertures at the same level to allow easy and accurate passage of the sutures through all four branches.
  - The two internal branches are at an 8-degree angle to each other, following the V-shaped anatomic form of the tendon.
  - A micrometric screw allows for varying the opening of the branches according to tendon morphology.
  - A straight needle with its attached suture is used with a needle driver, designed to provide a larger support surface to push the needle through the soft tissues and at the same time protect the surgeon by preventing perforation of the glove from the end of the needle.

Techniques

- Palpate the site of injury, represented by the gap or soft spot (TECH FIG 1A).
- The incision is paratendinous and medial (TECH FIG 1B), beginning at the soft spot and extending about 2.0 cm proximally.
- Gently retract the skin and subcutaneous tissue with hooks and identify the paratenon (TECH FIG 2A).
- Carefully open the sheath and tag each edge with a stay suture (TECH FIG 2B).
- Identify both stumps of the ruptured tendon (TECH FIG 3A) and carefully note the exact site of rupture.
- Introduce the Achillon in the closed position under the paratenon in a proximal direction, holding the tendon stump with a small clamp under the instrument (TECH FIG 3B).
- The tendon stump is located between the two internal branches (TECH FIG 3C).
- As the instrument is introduced, progressively widen it, holding the tendon stump firmly with the clamp.
- Confirm the position of the guide by external palpation; you should feel the tendon between the central (internal) branches of the instrument.
- Pass three sutures from lateral to medial, usually beginning with the most proximal hole of the instrument (TECH FIG 4A,B).
- Hold the end of each suture with a small clamp to keep them separate from each other.
- Slowly withdraw the instrument while progressively closing the branches (TECH FIG 5A).
- This maneuver results in the sutures sliding from an extracutaneous position to a peritendinous position, and thus the tendon itself is the only tissue held by the sutures (TECH FIG 5B).
- Apply traction to the three suture pairs to ensure they are firmly anchored in the tendon, and individually clamp them to prevent any confusion.
- Perform the same sequence on the distal stump: introduce the instrument under the tendon sheath and push it until it touches the calcaneus (TECH FIG 6A).
**TECH FIG 1** Illustration showing the skin incision, begun at the gap or soft spot (A), paratendinous and medial, and extended one and one-half to two centimeters proximally (B).

**TECH FIG 2** Illustration showing the sheath opened longitudinally in the midline (A) and a stay suture in place (B).

**TECH FIG 3** Illustration showing the forceps grasping the proximal tendon stump (A), and introduction of the instrument proximally under the paratenon (B,C).
Chapter 106  LIMITED OPEN REPAIR OF ACHILLES TENDON RUPTURES: PERSPECTIVE 1

**TECH FIG 4** • Illustration showing introduction of the first needle (A), and illustration showing all three sutures in the proximal tendon (B).

**TECH FIG 5** • Illustration showing the instrument being withdrawn (A) bringing the sutures from an extra-cutaneous to a peritendinous position (B).

**TECH FIG 6** • Illustration showing the exact same sequence performed on the distal stump. (A) Introduce the instrument under the tendon sheath and push it until it touches the calcaneus. (B) Illustration showing the sutures organized for tightening. (C) Illustration showing the tendon reduction performed under direct vision, confirming apposition of the tendon ends. (continued)
TECH FIG 6 • (continued) (D) Illustration showing closure of the skin with intradermal sutures.

**TECHNIQUES**

- All the sutures are now organized for tightening (TECH FIG 6B), which is carried out with corresponding pairs, and the tendon reduction is under direct visual control (TECH FIG 6C).
- If it is difficult to ascertain tendon length and reduction because the ends are too frayed, compare the tendon tension to the opposite leg.
- Close the tendon sheath, and then the skin with intradermal sutures (TECH FIG 6D).
- No drain is used.
- Apply a splint holding the ankle in 30 degrees of flexion before moving or waking up the patient.

**PEARLS AND PITFALLS**

- Be sure to note the soft spot or gap in the tendon to accurately plan the site of incision.
- Carefully open the paratenon and tag with stay sutures.
- Note exact site of rupture.
- Hold tendon stump with clamp while introducing Achillon instrument under the paratenon.
- Progressively open the instrument as it is introduced.
- After suture insertion carefully withdraw instrument while branches are progressively closed.
- Carefully organize all sutures for tying with ankle placed in equinus.
- Tendon reduction must be carefully controlled under direct vision.
- Orthosis is applied prior to moving or waking the patient.
- Failure to accurately locate the exact site of rupture prior to making incision.
- Failure to tag the paratenon with stay sutures.
- Failure to hold tendon stump with clamp while introducing Achillon instrument.
- Failure to progressively open the Achillon instrument as it is being inserted.
- Failure to keep each of the three sutures separate from each other.
- Failure to apply traction to the three suture pairs to ensure that they are firmly anchored in the tendon.
- Failure to individually clamp each of the three suture pairs to avoid confusion.
- Failure to control tendon reduction under direct visual control.
- Failure to apply orthosis prior to moving or waking the patient.

**POSTOPERATIVE CARE**

- Low-molecular-weight heparin (subcutaneous administration) is used to prevent deep vein thrombosis for 3 weeks postoperatively.
- Our early functional rehabilitation program, carefully supervised by the physical therapist, is divided into four stages.
- For the first 2 weeks patients are allowed partial weight bearing (30 to 45 pounds) and maintained in the splint full time.
- Then gentle ankle range of motion (flexion and extension) is begun, as well as thigh muscle exercises and the use of a stationary bicycle.
- The goal is to reach a neutral ankle position by the end of the third week.
- After 3 weeks, full weight bearing is allowed with continuous use of the protective splint.
- At the end of 8 weeks the splint is discontinued and weight bearing is allowed without any external support.
- A more intensive program of ankle range of motion, stretching, and isometric and proprioceptive exercises is instituted.
- Jogging is allowed at 3 months, and more demanding sports at 5 months.

**OUTCOMES**

- This limited open procedure with use of the Achillon instrument provides the advantage of an open repair but avoids the soft tissue problems associated with open repair.
- We published a prospective multicenter study in 2002 including 82 patients. Results showed no wound healing problems and no infections. No patient noted a sensory disturbance in the sural nerve distribution. All patients returned to their previous professional or sporting activities. The mean AOFAS score was 96 points (range 85 to 100 points).
- Complications occurred in three patients. Two of them were noncompliant and removed the orthosis within the first
3 weeks postoperatively, thus disrupting the repair by a new injury. One patient fell 12 weeks after the surgery and sustained a rerupture. All three new injuries were repaired with an open surgical procedure.

- Isokinetic results: The concentric peak torque was performed with the ankle in plantarflexion at 30°/s and 60°/s of angular velocity, after correction for dominance. There was no significant difference between the injured and uninvolved sides (Table 1). Endurance testing at 120°/s also revealed no difference between sides.

- Three recent reports describe similar excellent results using the exact surgical technique and Achillon instrument, thus providing further confirmation of its important role in the repair of acute Achilles tendon ruptures.

### COMPLICATIONS

- Disruption of the repair related to the patient’s noncompliance with the rehabilitation protocol (before the third month postoperatively)
- Rerupture of the healed Achilles tendon (after the third month postoperatively)
- Sural nerve injury
- Infection
- Deep venous thrombosis

### REFERENCES

DEFINITION
- Achilles tendon ruptures usually occur 3 to 4 cm above the calcaneal tuberosity.
- Although most injuries are “complete” ruptures, “partial” injuries have been described.
- An increasing number of reports in the recent literature favor operative treatment of a fresh rupture of the Achilles tendon; mini-invasive techniques are associated with a lower complication rate.

ANATOMY
- The Achilles tendon is about 9 cm long and 0.9 cm in diameter.
- The proximal part is composed of the gastrocnemius and soleus tendons.
- The distal portion inserts onto the posterior aspect of the tuberosity of the calcaneus.
- The Achilles tendon is surrounded by the paratenon, a delicate envelope that contributes to tendon vascularization.
- There is an area of poor vascularity located between 2.5 cm and 5 cm above the calcaneal tuberosity.

PATHOGENESIS
- Rupture of the Achilles tendon is a common injury among high-level athletes, recreational sports enthusiasts, or even sedentary individuals.
- Rupture of the Achilles tendon usually occurs during forceful dorsiflexion of the ankle.
- Patients often describe hearing or feeling a “pop” in the back of their ankle.
- Intratendinous degeneration can be found histologically.
- Association with cortisone and fluoroquinolone use has been demonstrated.
- This is typically a middle-age lesion, with peak incidence during the third and fourth decades.

NATURAL HISTORY
- There is a great amount of controversy concerning the treatment of an acute rupture of the Achilles tendon.
- Conservative treatment is found to have a higher rate of tendon rerupture and loss of strength due to the tendon healing in an elongated position.
- The major factor motivating surgeons to use a nonoperative approach appears to be avoiding the wound complications that occur with an operative repair.
- An increasing number of reports in the literature have tended to favor operative treatment of an acute rupture of the Achilles tendon.
- The exact type of operative procedure and the postoperative regimen remain controversial.
- If soft tissue complications are avoided, excellent functional results and full return to previous activity can be expected.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Physical examination reveals moderate swelling about the posterior aspect of the ankle.
- Patients are usually able to walk, although with moderate pain.
- With the patient prone, spontaneous excess dorsiflexion of the involved ankle is noted.
- In most cases a tender defect (“soft spot”) can be palpated in the Achilles tendon between 2.5 and 5 cm proximal to its insertion into the calcaneal tuberosity.
- The Thompson squeeze test is positive.
- Patients have difficulty walking on their toes or rising up on their heels.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- History and physical examination are sufficient to confirm the diagnosis.
- Since these injuries occur in a traumatic setting, plain radiographs of the ankle are strongly advised.
- There have been many reports of associated ankle fractures (medial malleolus).
- Calcaneal (tuberosity) avulsion will appear on the lateral view.
- Ultrasound and MRI are not required for the diagnosis of Achilles tendon rupture but may be of value when the diagnosis is questionable.

DIFFERENTIAL DIAGNOSIS
- Ankle sprain
- Ankle fracture
- Tennis leg (gastrocnemius tear)
- Acute paratenonitis
- Calcaneal (tuberosity) avulsion
- Plantaris tendon rupture

NONOPERATIVE MANAGEMENT
- Nonoperative treatment of acute Achilles tendon ruptures involves prolonged immobilization.
- Prolonged immobilization is associated with musculoskeletal changes (atrophy), increased time necessary for rehabilitation, and delayed return to work and preinjury activities.
- In randomized studies the rerupture rate has been found to be much higher in the nonoperative group.
- However, nonoperative treatment avoids surgical complications.
- Nonoperative treatment should be considered in elderly patients with limited functional expectations, patients with significant tobacco/alcohol addictions, patients under chronic cortisone treatment, patients with vascular disease, and patients with severe comorbidities (eg, renal failure).
SURGICAL MANAGEMENT

Preoperative Planning
- Plain films should be reviewed for fracture, avulsion, and calcific tendinopathy.
- All imaging studies are reviewed.
- Examination under anesthesia should be performed before positioning the patient to reconfirm the side of injury.

Preoperative Planning
- The surgeon should have available the Achillon® (Integra Life Sciences, Plainsboro, NJ) Achilles tendon repair system and two sets each of no. 2 nonabsorbable suture.
- The surgeon should be prepared to convert to an open procedure should the mini-open procedure not be feasible (severe shear injury pattern to the tendon).

Positioning
- The patient is placed in the prone position.
- The patient’s brachial plexi and ulnar nerves at the elbow are well protected from tension and untoward pressure, respectively.
- The patient’s genitalia must be protected.
- We routinely use a thigh tourniquet applied with the patient still supine on the stretcher before placing the patient in the prone position on the operating table.
- This facilitates effective tourniquet placement and avoids hyperextension of the back during tourniquet placement with the patient already prone.
- The feet are suspended over the end of the bed, with firm padding under the ankles.
- Both lower extremities are prepared into the operative field to determine the appropriate tension of the repair.

APPROACH AND IDENTIFICATION OF RUPTURED TENDON ENDS

- Mini-open incision (TECH FIG 1A)
  - Make a longitudinal skin incision about 2 cm long at the level of the rupture.
  - The incision is longitudinal in the event the procedure has to be converted to a full open procedure.

- Divide the paratenon to gain control of the ruptured tendon ends (TECH FIG 1B).
  - The plantaris tendon may occasionally be intact despite complete Achilles tendon rupture (TECH FIG 1C).
  - Tag the two tendon ends with suture (TECH FIG 1D,E).

TECH FIG 1 • A. Mini-open longitudinal incision directly over tendon rupture. B. Paratenon is divided to gain access to tendon ends. C. The plantaris tendon may remain intact despite complete Achilles tendon rupture. D. Tag sutures are placed on the mobilized tendon ends. E. Tension is applied to tag sutures, approximating the tendon ends.
PLACING PERMANENT SUTURES IN PROXIMAL ASPECT OF THE RUPTURED TENDON

- Using the proximal tag sutures, apply tension to the proximal tendon stump.
- Place retractors within the paratenon to define the interval between the tendon and the paratenon.
- Advance the Achillon device within the paratenon on the medial and lateral aspects of the tensioned proximal tendon (TECH FIG 2A,B).
- Typically, the tendon is palpable between the arms of the Achillon device.
- In succession from closest to farthest from the rupture, pass three sutures through the tensioned proximal tendon (TECH FIG 2C–F).

By retracting the Achillon device distally back into the wound, secure the sutures in the tendon, within the paratenon, and exiting within the wound (TECH FIG 3A,B).

- Tension must be placed on the sutures before proceeding to the next step to ensure the sutures are properly anchored in the proximal tendon (TECH FIG 3C).
- If the sutures pull out, repeat the three aforementioned steps, with careful palpation to be sure that the tendon is indeed between the arms of the Achillon device.

TECH FIG 2 • A. The Achillon device is advanced within the paratenon. B. Longitudinal tension placed on the tag suture while advancing the Achillon device facilitates optimal positioning of the tendon between the two arms of the Achillon device. C. The suture closest to the rupture is inserted first. Tension is maintained on the tag suture. D. The second suture is passed through the tendon. E. The third suture is passed. Tension is still maintained on the tag suture, and the tendon is centered between the two arms of the Achillon device that are within the paratenon. F. All three sutures are passed through the proximal tendon and organized.
By retracting the device from the wound, the three sets of sutures remain in the tendon, are within the paratenon, and exit at the wound. C. Longitudinal traction is placed on the sutures to ensure that they are secure within the proximal tendon.

PLACING PERMANENT SUTURES IN DISTAL ASPECT OF THE RUPTURED TENDON

- This is essentially the mirror image of placing sutures in the proximal tendon.
- With distal ruptures, the Achillon device must be advanced as close to the Achilles insertion on the calcaneus as possible to optimize the sutures’ purchase in tendon.
- Advance the Achillon device’s inner arms on either side of the Achilles tendon, within the paratenon (TECH FIG 4A).
  - Palpate to be sure that the tendon is indeed between the two arms of the Achillon device.
- Place the three sutures (similar to those in the proximal tendon), from closest to farthest from the rupture, into the distal tendon, with tension applied to the tag sutures (TECH FIG 4B–E).
- Retract the Achillon device from the wound, thereby bringing the three sutures within the paratenon and into the wound, ready for repairing the rupture (TECH FIG 4F).
- To ensure that the purchase of the sutures in the distal tendon is satisfactory, apply forceful tension to the sutures.
  - Tension should plantarflex the ankle (TECH FIG 4G).
  - Should the sutures pull out, repeat the steps described above so that acceptable purchase of the sutures in the distal tendon is achieved. In our opinion, palpation of the tendon between the arms of the Achillon device is helpful.

The Achillon device is advanced within the paratenon on the medial and lateral aspects of the distal tendon. (continued)
TECH FIG 4 • (continued) B–E. The three sutures are placed in the distal tendon and organized. F. The Achillon device is retracted from the wound so that the three sutures remain within the tendon, are within the paratenon, and exit at the wound. G. Longitudinal traction ensures that the sutures are secure within the distal tendon. Note the plantarflexion of the ankle with tension on the sutures.

**TENDON REPAIR**

- Approximate the two tendon ends by tensioning the sutures (TECH FIG 5A).
- The sutures must be carefully organized so that corresponding sutures are secured to one another.
- Passive plantarflexion of the ankle with a bump placed under the dorsum of the foot or maintained by an assistant takes tension off the tendon during repair.
- Secure the two sets of sutures closest to the rupture to one another first.
  - With tension maintained on one side, secure the other side with a surgeon’s knot (TECH FIG 5B).
  - Then secure the other side, applying tension first to remove residual slack in the suture (TECH FIG 5C).
- Repeat the suture technique described for the initial set of sutures for the other sets (TECH FIG 5D).
- Secure the intermediate set of sutures to one another, followed by the sets farthest from the rupture.
- If the sutures more distant from the rupture are overtensioned during the repair, then the tension gained with the previously secured sutures is forfeited. Therefore, overtensioning of each successive set of sutures is unnecessary.
- With the opposite, uninjured extremity prepared into the operative field, the resting tension of the repair may be compared to what is deemed physiologic (TECH FIG 5E).
- Setting the resting tension of the repair slightly greater than that of the contralateral extremity is acceptable and, in our opinion, preferred.
- Avoid undertensioning of the repair.
- As for flexor tendon repairs for the hand, we recommend reinforcing the repair with additional sutures directly at the rupture (TECH FIG 5F).
- In our opinion, this is important because the mini-open technique described above only serves the function of an internal splint. When the repair site is directly palpated after repair with only the three sets of sutures, invariably there is mostly suture at the repair site and relatively little collagen.
- We routinely perform this reinforcement with a running, absorbable suture.
- This not only reinforces the tendon repair but tends to bring more tendon collagen directly to the repair site.
- Place the running or alternatively multiple interrupted sutures circumferentially at the repair site.
TECH FIG 5 • A. The ruptured tendon ends are approximated by tensioning both sets of sutures. B. One side of the corresponding sutures closest to the rupture is tied. Tension should be maintained on the other side of this set of sutures. C. After removing slack in the suture, the other side of this first set of sutures is tied. D. The second and third set of sutures are secured. Over-tensioning of each successive set of sutures should be avoided since this will cause the previous set to lose its tension. E. The resting tension of the repair should match that of the other uninjured extremity. Preferably, the tension should be slightly greater in the repair. F. The repair is reinforced with a single running or multiple interrupted sutures directly at the rupture.

CLOSURE

- Repair the paratenon and fascial layer over the tendon to a “water-tight” closure (TECH FIG 6A).
- Reapproximate the subcutaneous layer and skin to a tensionless closure (TECH FIG 6B,C).

TECH FIG 6 • A. The paratenon and fascial layer are reapproximated. (continued)
POSTOPERATIVE CARE

- Low-molecular-weight heparin (subcutaneous administration) is used for prophylactic anticoagulation for 3 weeks postoperatively.
- We institute an early functional rehabilitation program, carefully supervised by the physical therapist, which is divided into four distinct stages.
- For the first 2 weeks patients are allowed partial weight bearing (30 to 45 pounds) and maintained in the splint full time.
- Then gentle ankle range of motion (flexion and extension) is begun, as well as thigh muscle exercises and the use of a stationary bicycle.
- The goal is to reach a neutral ankle position by the end of the third week.
- After 3 weeks, full weight bearing is allowed with continuous use of the protective splint.
- At the end of 8 weeks the splint is discontinued and weight bearing is allowed without any external support.
- A more intensive program of ankle range of motion, stretching, and isometric and proprioceptive exercises is instituted.
- Jogging is allowed at 3 months, and more demanding sports at 5 months.

OUTCOMES

- This limited open procedure with use of the Achillon instrument provides the advantage of an open repair but avoids the soft tissue problems associated with open repair.
- Assal et al published a prospective multicenter study including 82 patients. Results showed no wound healing problems and no infections. No patient noted a sensory disturbance in the sural nerve distribution. All patients returned to their previous professional or sporting activities. The mean AOFAS score was 96 points (range 85 to 100 points).
- Complications occurred in three patients. Two of them were noncompliant and removed the orthosis within the first 3 weeks postoperatively, thus disrupting the repair by a new injury. One patient fell 12 weeks after the surgery and sustained a rerupture. All three new injuries were repaired with an open surgical procedure.
- Isokinetic results: The concentric peak torque was performed with the ankle in plantarflexion at 30°/sec and 60°/sec of angular velocity, after correction for dominance. There was no significant difference between the injured and uninvolved sides. The endurance testing at 120°/sec also revealed no difference between sides.
- Three recent reports describe similar excellent results using the exact surgical technique and Achillon instrument, thus providing further confirmation of its important role in the repair of acute Achilles tendon ruptures.

REFERENCE

DEFINITION

- Achilles tendon ruptures typically occur about 2 to 6 cm proximal to the tendon’s insertion site on the calcaneus.
- This injury is relatively common among both high-performance athletes and the recreational athlete, particularly the “weekend warrior.”
- Ruptures occur most often in men between 30 and 50 years of age.

ANATOMY

- Tendinous portions of the gastrocnemius and soleus muscles coalesce to form the Achilles tendon (FIG 1).
- The plantaris muscle is a distinct entity medial to the Achilles tendon.
- The soleus tendon originates as a band proximally on the posterior surface of its muscle, and the gastrocnemius tendon emerges from the distal margin of the muscle bellies.
- The length of the tendon formed from the gastrocnemius and soleus range from 11 to 26 cm and 3 to 11 cm, respectively.

PATHOGENESIS

- Ruptures occur most commonly during athletic activities.
- Both hyperpronation and cavus foot alignment are associated with Achilles tendon injuries. The cavus foot is thought to place more stress on the lateral side of the Achilles tendon and to absorb shock poorly.
- Inconsistent training, including sudden increases in training intensity; excessive training; training on hard surfaces; and running on sloping, hard, or slippery roads have been implicated in Achilles tendon problems.
- Mechanisms of injury, leading to eccentric loads on the Achilles tendon, include pushing off with the weight-bearing forefoot while extending the knee, unexpected dorsiflexion of the ankle, or violent dorsiflexion of a plantarflexed foot.
- With normal aging, the Achilles tendon decreases in cell density, collagen fibril diameter and density, and fiber waviness. These changes may make the aging athlete more susceptible to injury.
- Spontaneous rupture of the Achilles tendon has been associated with corticosteroid use, inflammatory or autoimmune conditions, collagen abnormalities, infectious diseases, neurologic conditions, and fluoroquinolone use.

NATURAL HISTORY

- Chronic Achilles tendon injuries typically result in the patient’s inability to complete everyday tasks such as climbing stairs.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient reports sudden pain in the affected leg.
- Some patients recall an audible pop or snap.
With Achilles tendon ruptures, patients occasionally experience a sensation as though they were “kicked” or “hit” in the injured calf. Patients report an inability to bear weight and weakness of the affected lower extremity.

Physical examination should include the following:
- Palpation of gap: Palpate along the posterior aspect of the lower leg, and a gap may be felt along the course of the tendon.
  - Positive: appreciable gap
- Thompson test: With the patient prone, squeeze the proximal portion of the calf.
  - Positive: no plantarflexion of the ankle
- False-positive results may be obtained with an intact plantaris tendon.
- Knee flexion test: With the patient prone, have him or her actively flex both knees to 90 degrees.
  - Positive: asymmetric resting tension of both ankles; the affected foot may even fall into neutral or dorsiflexion.
- Needle test: Insert a hypodermic needle into the calf medial to the midline and 10 cm proximal to the insertion of the tendon. The ankle is put through passive range of motion.
  - Positive: the needle points proximally on dorsiflexion.
  - This test is usually only performed if there remains a high index of suspicion with the other tests being equivocal.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs (rarely required in evaluation of Achilles tendon ruptures)
  - In a lateral radiograph, the fat-filled triangular space (ie, Kager’s triangle) anterior to the Achilles tendon and between the posterior aspect of the tibia and the superior aspect of the calcaneus loses its regular configuration.
- MRI (FIG 2) (rarely required in evaluation of Achilles tendon ruptures)
  - T1- and T2-weighted images in the axial and sagittal planes should be used to evaluate Achilles tendon ruptures.
  - T1-weighted: a complete rupture of the Achilles tendon is identified as a disruption of the signal within the tendon.
  - T2-weighted: a complete rupture is demonstrated as a generalized increase in signal intensity, and the edema and hemorrhage at the site of the rupture are seen as an area of high signal intensity.10
- Ultrasound (useful because it can be performed in the office setting)
  - Rupture seen as an acoustic vacuum with thick irregular edges
  - May also be used for postoperative evaluation to assess the structure of the tendon and integrity of repair14

**DIFFERENTIAL DIAGNOSIS**

- Typically, rupture of the Achilles tendon does not conjure up a differential diagnosis.
- Because four other muscles plantarflex the ankle, Achilles tendon ruptures may be initially mistaken for ankle sprains; although increasingly less common, it has been reported that up to 20% of Achilles tendon ruptures may be missed by the first doctor to examine the patient.9

**NONOPERATIVE MANAGEMENT**

- Equinus short-leg cast or plantarflexed cam boot for 6 to 8 weeks
- At 6 to 8 weeks, start gentle range-of-motion exercises.
- A heel lift is used in the transition to wearing normal shoes.
- The patient may return to running in 4 to 6 months.
- Considered for elderly or sedentary patients, poor surgical candidates (vascular compromise and/or poor skin quality), or patients favoring nonoperative treatment
- The rerupture rate after nonoperative management is about 12.1%, compared with the rerupture rate for surgical repair, which is only 2.2%.12

**SURGICAL MANAGEMENT**

- In our hands, percutaneous repair is reserved for acute tears, a minimal tendon gap, and compliant patients.
- Advantages of percutaneous repair are as follows:
  - Low risk of wound complications
  - Preservation of blood supply for tendon healing
  - Performed as outpatient procedure
  - Requires only local anesthetic
  - Maintenance of tendon length
  - Earlier return to function when compared to closed treatment
- Disadvantages include:
  - Potential sural nerve injury
  - Higher rerupture rate versus open repair
  - Limited patient population
  - Need for compliance postoperatively
- Percutaneous repair is contraindicated in chronic tears, tendon gap, noncompliant patients, and high-level athletes (relative).

**Positioning**

- Prone position
- No tourniquet
- Injured foot in about 25 degrees of plantarflexion

**Approach**

- Percutaneous
PERCUTANEOUS ACHILLES TENDON REPAIR

- The repair is performed under local anesthesia (TECH FIG 1).
- A size 0 monofilament polydioxanone suture with two Keith needles, one on either end, is used.
- Medial and lateral stab incisions are made on either side of the Achilles tendon using a no. 15 blade in the following locations: at the level of the rupture; 2.5 cm and 5 cm above the rupture; and 2.5 cm below the rupture. A total of eight stab incisions are made (TECH FIG 2).
- The subcutaneous tissues at each incision site are spread using a hemostat.
- Beginning at the most proximal lateral wound, the needle is passed transversely, and the suture is then manipulated until equal lengths are established on either side (TECH FIG 3).
- The suture is then advanced distally from both sides through the ipsilateral proximal incisions in a crisscross fashion through the tendon at 45-degree angles (TECH FIG 4).
- The previous step is repeated at both 5 cm and 2.5 cm proximal to the rupture (TECH FIG 5).
- The suture, now emerging at the level of the rupture, is then tensioned to ensure that it is secured in the proximal Achilles tendon stump.
- The suture is then advanced distally across the rupture site, in a fashion similar to the previous step (TECH FIG 6).
- The lateral suture is passed through the ipsilateral incision transversely, from lateral to medial, where the ends of the sutures are pulled simultaneously, and then tied; closing the tendon gap.
- A hemostat is used to bury the knot and to be sure there is no skin puckering at any of the incision sites.
- Staples are placed to approximate the skin.

TECH FIG 1 • Local anesthetic used for the procedure.

TECH FIG 2 • Incision locations: at the level of the tear, 2.5 cm and 5 cm above the tear, and 2.5 cm below the tear.

TECH FIG 3 • The needle is passed transversely, and the suture is manipulated until equal lengths are obtained.

TECH FIG 5 • Crisscross fashion to advance the suture distally through the tendon at 45 degree angles.

TECH FIG 6 • Suture is advanced distally across the rupture site.

PEARLS AND PITFALLS

- No need for antibiotic prophylaxis
- Perform technique with two Keith needles.
- To avoid sural nerve injury, use the “nick and spread” technique or lengthen the lateral incisions at the level of the rupture and at the musculotendinous junction to 1.0 to 1.5 cm. Use two small Langenbeck retractors to further visualize the location of the sural nerve lying superficial to the fascia.16

POSTOPERATIVE CARE

- Throughout the rehabilitation period: light active dorsiflexion, muscle strengthening, proprioception exercises, stationary cycling with heel push, soft tissue treatments
- For the first 2 weeks: immobilization and non–weight-bearing of the foot and ankle in an adjustable boot locked in 20 degrees of plantarflexion (FIG 3). Gentle plantigrade movement of the foot, straight leg raises, and knee range of motion are begun.
- Week 2: the boot is adjusted to 10 degrees of plantarflexion.
- Week 4: Orthosis is adjusted to neutral; partial weight bearing is initiated.
Week 6: Full weight bearing is permitted.
Week 8: The foot is placed in a shoe with a heel lift.
Month 3: The patient starts closed-chain exercises, cycling, and elliptical trainer.
Month 6: Running, jumping, and sports activities may be resumed.

OUTCOMES

- Retrospective review of 10 consecutive patients with acute Achilles tendon ruptures:
  - No reruptures
  - No major complications
  - One sural nerve injury
  - Mean return to full activity at 6.1 months
  - American Orthopaedic Foot and Ankle Society (AOFAS) ankle hindfoot rating: average score 94
  - Mean difference of 1.58 cm in calf circumference, with the involved leg having the smaller circumference
  - Mean plantarflexion peak torque of the uninvolved leg having the smaller circumference
  - Mean return to work a mean of 4 months after percutaneous repair.
  - 1 patient (out of 22) experienced a rerupture after percutaneous repair.

The open repair group had an 8.6% incidence of wound complications (no wound dehiscence occurred in the percutaneous repair group).

- Two patients out of 35 experienced rerupture after open repair; 1 patient (out of 22) experienced a rerupture after percutaneous repair.

- Patients returned to work a mean of 4 months after open repair and 3.75 months after the Webb-Bannister percutaneous repair.

- No sural nerve complications occurred.

COMPLICATIONS

- Sural nerve injury
- Palpable suture knot which may necessitate excision
- Rerupture
- Deep venous thrombosis

REFERENCES

DEFINITION
■ Rupture of the Achilles tendon is common.
■ More than 20% of acute injuries are misdiagnosed, leading to chronic or neglected ruptures.4

ANATOMY
■ The two heads of the gastrocnemius arise from the condyles of the femur, the fleshy part of the muscle extending to about the midcalf. As the muscle fibers descend they insert into a broad aponeurosis that contracts and receives the tendon of the soleus on its deep surface to form the Achilles tendon.9
■ The Achilles tendon is the thickest and strongest tendon in the body. About 15 cm long, it originates in the midcalf and extends distally to insert into the posterior surface of the calcaneus. It receives muscle fibers from the soleus on its anterior surface throughout its length.9

PATHOGENESIS
■ The most common mechanism of injury is pushing off with the weight-bearing forefoot while extending the knee. Sudden unexpected dorsiflexion of the ankle or violent dorsiflexion of a plantarflexed foot may also result in ruptures.5
■ Corticosteroids, fluoroquinolone use, tendon pathology, and poor vascularity of the Achilles tendon have been associated with rupture.5

NATURAL HISTORY
■ A delay in treatment of Achilles tendon rupture results in the formation of a discrete gap. The gap between ruptured tendon ends may fill with fibrous nonfunctional scar. Patients find walking and ascending stairs difficult, and standing on tiptoes on the affected limb impossible.

PATIENT HISTORY AND PHYSICAL FINDINGS
■ Patients often give a history of feeling a blow to the posterior aspect of the leg and may describe an audible snap followed by pain and inability to bear weight.
■ In acute tendon ruptures, a gap in the Achilles tendon is usually palpable. In delayed presentation, edema may fill this gap, making palpation unreliable.
■ Active plantarflexion of the foot is usually preserved due to the action of the tibialis posterior and the long toe flexors.
■ The calf squeeze test, first described by Simmonds in 19577 but often credited to Thompson, is performed with the patient prone and the ankles clear of the table. The examiner squeezes the fleshy part of the calf, causing deformation of the soleus, and resulting in plantarflexion of the foot if the Achilles tendon is intact. The affected leg should be compared to the contralateral leg.
■ The knee flexion test is performed with the patient prone and the ankles clear of the table. The patient is asked to actively flex the knee to 90 degrees. During this movement the foot on the affected side falls into neutral or dorsiflexion and a rupture of the Achilles tendon can be diagnosed.6

IMAGING AND OTHER DIAGNOSTIC STUDIES
■ The diagnosis of acute ruptures is usually a clinical one.
■ Plain lateral radiographs may reveal an irregular configuration of the fat-filled triangular space anterior to the Achilles tendon and between the posterior aspect of the tibia and the superior aspect of the calcaneus.

DIFFERENTIAL DIAGNOSIS
■ Ankle sprain

NONOPERATIVE MANAGEMENT
■ Acute ruptures may be managed conservatively in an equinus cast for 6 to 8 weeks before being converted to a functional brace.
■ Conservative management may result in tendon lengthening, thus altering function.1

SURGICAL MANAGEMENT
■ Percutaneous repair3 was originally described as a compromise between open surgery and conservative management. A percutaneous repair aims to provide the optimal functional outcome of open repair while decreasing the problems associated with it in terms of wound healing and skin breakdown.

Preoperative Planning
■ Once the diagnosis is made, an assessment of general health and comorbidities should be performed.
■ The preoperative functional status should be noted.
■ The skin quality and neurovascular status of the affected limb should be examined.
■ The status of the sural nerve should be documented.
■ We recommend that the patient be maintained on deep venous thrombosis prophylaxis.
■ The procedure can be performed under general anesthesia or a local anesthetic, with a 50:50 mixture of 10 mL of 2% lignocaine hydrochloride (Antigen Pharmaceuticals Ltd, Roscrea, Ireland) and 10 mL of 0.25% bupivacaine hydrochloride (Astra Pharmaceuticals Ltd, Kings Langley, England) instilled into an area of between 8 and 10 cm around the ruptured Achilles tendon.

Positioning
■ The patient is placed prone, and a pillow is placed beneath the anterior aspect of the ankles to allow the feet to hang free.
■ The operating table is angled down 20 degrees cranially to reduce venous pooling in the feet and ankles.
■ A tourniquet is not necessary for this procedure.
Approach

- Previous approaches such as those described by Ma and Griffith\(^3\) using three medial and three lateral stab incisions have been abandoned in light of the relatively increased incidence of sural nerve entrapment.
- We will present two techniques that we employ. The first is an approach similar to that described by Webb and Bannister.\(^8\) Three 3-cm transverse skin incisions are made. The middle one is made over the palpable gap, and the proximal and distal incisions are placed 4 cm proximal and distal to the middle incision respectively (FIG 1). The second is currently our favored technique: the results for acute ruptures are as good as the first technique, but it is even less invasive.
- In the first technique the proximal incision is made more medial to the others to avoid the sural nerve. The stab incisions used in the five-incision latter procedure do not usually give rise to sural nerve problems.

**MINIMALLY INVASIVE REPAIR OF ACUTE ACHILLES TENDON RUPTURE WITH MODIFIED KESSLER SUTURE PATTERN**

- Use a small hemostat to free the tendon sheath from the overlying subcutaneous tissue.
- Pass a 1 PDS II (Ethicon, Johnson & Johnson Intl, Brussels, Belgium) double-strand suture on a long curved needle transversely through the distal incision, passing through the substance of the tendon and out through the same incision (TECH FIG 1A).
- Reintroduce the needle medially into the distal incision through a different entry point in the tendon, and pass it longitudinally through the tendon to lock the tendon. Direct the needle toward the middle incision and out through the ruptured tendon end (TECH FIG 1B).
- Rethread the suture still protruding from the distal incision onto the needle and reintroduce it laterally into the distal incision stump of the tendon (TECH FIG 1C).
- The procedure is repeated in the proximal stump (TECH FIG 1D).
- The suture ends are then tied with the ankle in physiologic plantarflexion.
incision and into the tendon. Pass it proximally through the tendon to exit from the middle incision (TECH FIG 1C).
- Apply traction to the suture to ensure satisfactory grip of the tendon.
- Carry out the same procedure for the proximal stump of the ruptured tendon (TECH FIG 1D).
- A further 1 PDS II (Ethicon) double-stranded suture can be placed in the tendon ends as described above to produce an eight-strand repair.
- Tie the sutures with the ankle in physiologic plantarflexion (TECH FIG 1E).
- Assess the tension by observing the contralateral limb as the sutures are tied.
- Close the skin wounds with undyed subcuticular 3-0 Vicryl (Ethicon, Edinburgh, UK) suture and apply nonadherent dressings.
- Apply a full plaster-of-Paris cast in the operating room with the ankle in physiologic equinus.

PERCUTANEOUS REPAIR OF ACUTE ACHILLES TENDON RUPTURE USING FIVE STAB INCISIONS

- Local anesthetic infiltration is used. Instill a 50:50 mixture of 10 mL of 2% lignocaine hydrochloride (Antigen Pharmaceuticals) and 10 mL of 0.25% bupivacaine hydrochloride (Astra Pharmaceuticals) into an area 8 to 10 cm around the ruptured Achilles tendon.
- The patient is placed prone, and a pillow is placed beneath the anterior aspect of the ankles to allow the feet to hang free.
- Angle the operating table down about 20 degrees cranially to reduce venous pooling in the feet and ankles.
- The affected leg is prepared with antiseptic and sterile draped. We do not use a tourniquet.
- Make five stab incisions over the Achilles tendon (TECH FIG 2A). The first is directly over the palpable defect and measures about 2 cm in a transverse direction.
- The other incisions are about 4 cm proximal and 4 cm distal to the first incision and are vertical 1-cm stab incisions on the medial and lateral aspect of the Achilles tendon.
- We advocate blunt dissection with a small hemostat directly onto the Achilles tendon. This avoids damaging the sural nerve, which crosses the lateral border of the Achilles tendon about 10 cm proximal to its insertion into the calcaneus.
- Use a small hemostat to free the tendon sheath from the overlying subcutaneous tissue (Tech Fig 2A).
- Pass a 1 PDS II (Ethicon) double-stranded suture on a long curved needle transversely through the lateral proximal stab incision, passing it through the substance of the tendon and out through the medial proximal stab incision (TECH FIG 2B).
- Reintroduce the needle into the medial proximal stab incision through a different entry point in the tendon and pass it longitudinally and distally through the tendon to lock into the tendon. Direct the needle toward the middle incision and out through the ruptured tendon end (TECH FIG 2C).
- Retread the suture that is still protruding from the lateral proximal stab incision onto the needle and reintroduce it via the lateral proximal stab incision into the tendon substance. Also pass it longitudinally and distally through the tendon to exit from the middle incision. Apply traction to the suture to ensure a satisfactory grip within the tendon. If the suture pulls through, repeat the procedure. We sometimes use an eight-stranded method by doubling the sutures used for the Kessler-type technique we are describing.
- Carry out the same procedure for the distal half of the ruptured tendon.
- Tie the sutures with the ankle in physiologic plantarflexion and bury them into the tissues using a hemostat (TECH FIG 2E).
- Close the skin wounds with undyed subcuticular 3-0 Vicryl (Ethicon) suture and apply nonadherent dressings.
- Apply a full plaster-of-Paris cast in the operating room with the ankle in physiologic equinus. Split the cast on both medial and lateral sides to allow for swelling (TECH FIG 2F).
POSTOPERATIVE CARE

- The postoperative care regimen and rehabilitation are similar for both techniques.
- Patients are discharged on the same day of the operation.
- The neurovascular status of the limb is assessed.
- After assessment by a physiotherapist, making sure that the patient is safe and comfortable in the cast, the patient can be discharged.
- The full cast is retained for 2 weeks, and patients are allowed to bear weight as comfort allows. During the period in the cast, patients are advised to perform gentle isometric contractions of the gastroc–soleus complex.
- At 2 weeks, patients are reviewed as outpatients, the cast is split, and the wounds are inspected. An anterior splint is worn with the foot in plantarflexion for a further 4 weeks.
- Patients are advised to mobilize with partial weight bearing initially, increasing to weight bearing as able by 4 weeks.
- The splint is then removed, and physiotherapy follow-up for gentle mobilization is arranged. Light weight-bearing exercise can be started 2 weeks after cast removal, and the patient should be fully weight bearing by 10 weeks.

OUTCOMES

- Lim et al., in a randomized controlled trial, advocated percutaneous repair over open surgical techniques after finding no significant differences in functional results, a lower infection rate with the percutaneous repair, and a subjectively more acceptable cosmetic appearance of the percutaneous operative site.
- We reviewed 31 patients who underwent percutaneous repair in our tertiary referral center between 2001 and 2003. Eleven patients (35.5%) received general anesthesia and 20 (64.5%) had local anesthesia. The average length of cast time was 5.97 weeks. One (3.2%) patient sustained a...
major complication, a small pulmonary embolism, which was managed successfully with warfarin. There were no reruptures, and six (19.4%) patients had minor wound complications.

COMPLICATIONS

- Early complications include sural nerve damage and hematoma.
- Intermediate superficial and deep wound infections may occur.
- The most important late complication is rerupture.

REFERENCES

DEFINITION

- Achilles tendon rupture results in loss of plantarflexion function of the ankle through disruption of the gastrocnemius–soleus–Achilles (GSA) mechanism.
- Chronic rupture is usually defined as a rupture not appropriately treated within 8 weeks of injury.
- Chronic or neglected ruptures result in retraction of the proximal myotendinous portion and diastasis between the ruptured tendon ends.
- Functional deficits result from loss of plantarflexion strength and dorsiflexion; check reign of the GSA mechanism.

ANATOMY

- The triceps surae complex is composed of the two heads of the gastrocnemius and the soleus muscle combining to form a single tendon—the Achilles tendon, making up the GSA complex.
- The GSA complex originates from the distal femoral condyles and inserts into the posterior calcaneal tuberosity, making it one of the few muscle–tendon complexes to cross three joints (knee, ankle, and subtalar joints) in the human body.
- The tendon is loosely surrounded by a paratenon, which allows the tendon to slide about 1.5 cm.
- The blood supply to the tendon emanates from the muscle proximally and the calcaneal insertion distally, leaving a watershed area of relatively avascular tendon 4 to 5 cm from the calcaneal insertion.

PATHOGENESIS

- Seventy-five percent of Achilles tendon ruptures occur during sporting activities.
- A history of prior Achilles tendinitis is present in about 15% of ruptures.
- Ruptures occur most commonly in the 30- to 40-year age group, with a male predominance.
- Eighty percent of Achilles tendon ruptures occur in the watershed area 2 to 6 cm above the insertion.
- Mechanism of injury resulting in rupture can be forceful plantarflexion or hyperdorsiflexion of the ankle.
- Achilles tendon ruptures are frequently missed or misdiagnosed as ankle sprains on initial assessment.
- Failure of immobilization or repair will allow continued contracture of the gastrocnemius muscle, resulting in retraction of the proximal myotendinous portion of the GSA complex and subsequently in the development of a gap between the tendon ends.

NATURAL HISTORY

- Missed or neglected ruptures of the Achilles tendon result in plantarflexion weakness and loss of the dorsiflexion; check reign of the GSA complex.
- Without treatment patients develop gait dysfunction, particularly walking up stairs, inclines, or ladders, as well as balance difficulties, with a tendency to fall forward.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients frequently recall the primary event, and often describe feeling like they had been “shot” or “hit” on the back of the heel when the rupture occurred.
- Silent or spontaneous ruptures may occur in the presence of systemic inflammatory diseases, steroid use, or chronic underlying Achilles tendinosis.
- Patients are usually able to walk on the limb and plantarflex the ankle without significant pain despite the chronic rupture.
- Primary complaints are:
  - Weakness of plantarflexion (walking up inclines, stairs, ladders)
  - Gait and balance difficulties
- Clinical examination
  - Inability to walk on tiptoes
  - Inability to perform a single-leg toe raise (difficulty with double-leg raise)
- Direct evaluation should be performed with the patient lying prone with both knees flexed to 90 degrees (both sides are examined and compared):
  - Decreased resting tension of the Achilles tendon (normal resting tension of the unaffected side holds the ankle at 20 to 30 degrees of plantarflexion, while the ruptured side will usually be neutral [zero degrees plantarflexion]).
  - Hyperdorsiflexibility of the ankle compared to the unaffected side
  - Plantarflexion may be present (due to the effect of the posterior tibial tendon, flexor hallucis longus [FHL], and tibialis posterior) but is weaker than the unaffected side.
- A palpable gap may be present between the ruptured tendon ends (FIG 1) when the tendon is followed from the insertion proximally. Careful palpation can usually detect the proximal end, and the gap can be estimated, although it is difficult to measure clinically.
- The Thompson test (squeezing the calf) will not result in symmetrical ankle plantarflexion (compared to the unaffected side), although some degree of plantarflexion is usually present in chronic rupture cases.
IMAGING AND OTHER DIAGNOSTIC STUDIES
- The diagnosis of an Achilles tendon rupture (acute or chronic or neglected) can usually be made on careful clinical evaluation alone.
- If one is uncertain or wishes to better quantify the rupture gap, ultrasound or MRI can be performed.
- Both tests are highly reliable in confirming the diagnosis and in obtaining an accurate measurement of the gap.
- No difference in diagnostic accuracy has been shown, although the MRI may yield more information about the degree of atrophy and fibrosis within the gastrocsoleus muscle.
- This will not affect the treatment options but may help prognosticate the outcome of reconstruction.
- MRI evaluation is useful in neglected ruptures to quantify the gap between the tendon ends.

NONOPERATIVE MANAGEMENT
- Brace management can be used for patients who are not candidates for surgical reconstruction.
- These include patients with medical risk factors, poor distal circulation, and impaired wound healing potential (including patients on steroids or immunosuppressive medications, and those with diabetes mellitus).
- Patients with more moderate functional deficits, with low physical demands, may choose nonsurgical management.
- Management consists of a custom-molded ankle–foot orthosis (MAFO) made of polypropylene.
- An ankle hinge spring-loaded MAFO can be fashioned to add plantarflexion torque and further aid push-off.
- Long-term braces tend to be poorly tolerated in many patients with more active lifestyles.

SURGICAL MANAGEMENT
- The choice of surgical reconstruction depends on the size of the rupture gap. The ability to mobilize the retracted muscle tends to be the major limiting factor.
- Defects less than 1 cm can usually be mobilized and repaired with end-to-end anastomosis.
- For defects of 1 to 3 cm, direct end-to-end anastomosis can usually be obtained. Stretching of the retracted muscle is usually required via longitudinal traction over about a 10-minute time period to close the gap.
- Defects of 3 to 7 cm require an advancement procedure of the Achilles tendon, performed as a V-to-Y lengthening. Further augmentation with a FHL tendon transfer results in additional strength and function of the repair. This technique will be outlined in more detail below.
- For defects of more than 7 cm, reconstruction involves either an Achilles turndown procedure (if enough tendinous tissue is available proximally) or an allograft replacement of the Achilles tendon.

Preoperative Planning
- MRI or ultrasound should be reviewed to determine the gap size and to aid in the location of the ruptured ends.
- Examination under anesthesia should be performed as described above.
- General endotracheal or spinal anesthesia can be used for this procedure.
- Surgery is usually performed on an outpatient basis.

Positioning
- Once the patient is anesthetized, a well-padded thigh tourniquet should be applied.
- It is technically easier to apply the tourniquet while the patient is still in a supine position.
- The surgeon must ensure that the connection for the tubing is placed posteriorly or laterally to allow attachment after positioning, and to prevent pressure problems from the patient lying on the connection or tubing.
- A calf tourniquet should not be used because it may limit the surgeon’s exposure and puts squeeze on the gastrocsoleus muscle, preventing muscle mobilization.
- The patient is turned into a prone position.
- Chest rolls should be used if the patient is asleep for the procedure (this is usually not needed if the procedure is performed under spinal anesthesia).
- Both lower extremities should be prepared and draped. This allows the unaffected side to be used as a template against which the resting tension of the repair can be assessed.
- The legs should be prepared and draped to above the level of the knee joints.

FIG 1 • A large palpable gap can usually be felt between the ruptured ends.

FIG 2 • MRI shows a neglected Achilles tendon rupture. The white arrows indicate the proximal and distal stump ends, with a 5-cm gap.
INCISION

- After Esmarch exsanguination of the limb, the tourniquet is inflated and left inflated until a compressive dressing has been applied at the end of the procedure.
- The approach to the repair involves an extensile incision over the posterior calf (TECH FIG 1A).
- Place the distal incision, over the region of the rupture and gap, medial to the Achilles tendon.
  - This prevents injury to the sural nerve, which runs 5 mm lateral to the Achilles tendon, and keeps the incision away from the posterior aspect of the heel, where it could rub against a shoe counter, causing irritation.
  - This usually involves the most distal 10 cm of the incision.
- Continue the incision sharply full thickness down to and through the paratenon. Reflect the paratenon off the tendon and preserve it for later repair.
- Proximally, curve the incision centrally and continue it up the posterior midline of the calf to the proximal extent of the myotendinous junction.
- The sural nerve in the calf crosses from lateral to central over the myotendinous junction region and then passes under the medial head of the gastrocnemius muscle proximally.
  - The nerve must be identified (TECH FIG 1B) within the subcutaneous tissue, retracted, and protected throughout the rest of the procedure.
  - The nerve runs with the lesser saphenous vein, which aids in identifying its location, and the vein too should be preserved if possible.
- Expose the entire tendon up to a level proximal to the myotendinous junction.
- Carefully reflect the paratenon off the proximal tendon and preserve it for later repair.

MEASUREMENT OF THE GAP

- Once the ruptured region is identified, measure the gap. A scar pseudo-tendon is frequently identified within the rupture gap, and this should be resected together with the nonviable ends of the tendon.
- Measure the true tendon gap (TECH FIG 2) with the knee flexed to 30 degrees and the ankle plantarflexed to 20 degrees to match the resting tension of the unaffected side.

V-TO-Y LENGTHENING

- Make an inverted-V incision through the tendinous portion only of the myotendinous junction of the GSA complex.
- Leave the underlying muscle fibers intact and attached to the proximal muscle body.
- Place the apex of the V in the midline at the most proximal portion of the myotendinous junction.
- The limbs of the V then diverge to exit at the medial and lateral borders of the tendon, respectively. The V limbs should be at least one-and-a-half times longer than the length of the measured gap (TECH FIG 3A). In our experience with these more extensive gaps (greater than 5 cm), we recommend that the limbs of the V are at least twice the length of the rupture gap to allow adequate lengthening to be obtained.
- Use a heavy braided nonabsorbable suture (we use no. 2 Fiberwire [Arthrex Inc., Naples, FL], but no. 5 Ethibond [Ethicon-J&J, Piscataway, NJ] can also be used) for the end-to-end tendon anastomosis after the lengthening.
Chapter 110  CHRONIC ACHILLES TENDON RUPTURES USING V-Y ADVANCEMENT AND FHL TRANSFER

- Use a locking Krackow technique, placing at least five locking loops in a running style along the medial and lateral aspect of the tendon, on each end of the rupture (TECH FIG 3B).
- Insert the suture into the free end of the tendon and then loop it in a locking pattern up the side of the tendon. Attempt to capture about one third to one half of the tendon width with each loop of the suture. Once five loops have been thrown, pass the suture through the substance of the tendon, exiting at the same level on the opposite side of the tendon. Throw another five locking loops toward the end of the tendon, with the suture exiting again at the free end of the tendon.
- We have found that a single continuous suture is adequate for the repair.

- Apply traction to the suture material within the proximal tendon stump in a distally directed longitudinal direction (TECH FIG 3C). This is a firm continuous traction, allowing the muscle fibers to gently stretch out and slide. A weight can be hung over the end of the table to facilitate traction. While some force is required to create this advancement slide, take patience and great care not to detach the tendon from the muscle, which would devascularize the tendon.
- While this is being applied, gently tease the muscle fibers of the myotendinous junction longitudinally, allowing the myotendinous junction to slide distally.
- Continue traction until the tendon ends can be approximated with the ankle resting tension matching the unaffected side.
- Repair the V incision in the tendon, creating an inverted-Y configuration (TECH FIG 3D). The long arm of the inverted Y is the length that the tendon has been elongated—equal to the length of the measured gap.

FLEXOR HALLUCIS LONGUS AUGMENTATION

- Before repairing the ends of the tendon together, harvest the FHL tendon and transfer it to augment the repair.
- The FHL muscle lies in the deep posterior compartment of the leg immediately posterior to the Achilles tendon in this region. With the Achilles tendon and muscle belly reflected, the deep posterior compartment fascia can be incised and released, exposing the FHL muscle and tendon. The muscle of the FHL usually extends distally down to the level of the tibiotalar joint, making it easy to identify (it is frequently referred to as “beef at the heel”) (TECH FIG 4A). Identify the tendon at the distal end of the muscle and digitally retract it.
The hallux should be seen to flex on traction of the tendon, confirming that the correct tendon has been identified. Immediately medial to the FHL muscle and tendon is the medial neurovascular bundle (including the tibial nerve and posterior tibial artery); take care to avoid injury to these structures. Follow the FHL tendon around the medial malleolus (dissection should be performed along the lateral aspect of the tendon as the sheath is released behind the ankle to avoid inadvertent injury to the bundle) (TECH FIG 4B).

With the ankle and hallux held fully flexed and maximum traction placed on the FHL tendon, transect the tendon as distally as possible. In almost all cases, adequate length of tendon can be obtained using this technique (TECH FIG 4C).

Measure the tendon diameter (TECH FIG 4D); a corresponding-sized bone tunnel will be drilled into the posterior tubercle of the calcaneus directly anterior to the attachment of the distal stump of the Achilles tendon.

The hallux should be seen to flex on traction of the tendon within the deep posterior compartment of the leg. B. The FHL tendon is retracted and followed to the level of the medial malleolus. C. The FHL tendon is transected at the medial malleolar level, leaving adequate tendon length for the transfer. D. The FHL tendon diameter is measured, allowing accurate tunnel sizing. E. A Beath pin is drilled through the calcaneus immediately anterior to the Achilles tendon insertion. F. The Beath pin is overdrilled with an appropriately sized cannulated drill bit so as to create the bone tunnel for the FHL tendon. G. The FHL tendon is pulled into the bone tunnel via the attached suture material and pulled to an appropriate tension.
Place a Krackow locking suture in the distal portion of the FHL tendon and pull the tendon into the bone tunnel. This is done using a Beath pin (long pin with a suture eyelet), pulling the suture ends out of the plantar aspect of the foot (TECH FIG 4E). Create the bone tunnel with a size-specific cannulated drill bit over the Beath pin (TECH FIG 4F). Traction can be applied to the suture to hold the tendon within the bone tunnel at the appropriate tension.

**ALTERNATE TECHNIQUE FOR FLEXOR HALLUCIS LONGUS HARVEST**

- If additional length of the FHL tendon is required, the tendon can be harvested from the midfoot.
- This requires a separate incision to be made over the medial side of the foot from the plantar aspect of the talonavicular joint extending to the midshaft of the first metatarsal.
- Reflect the abductor hallucis and flexor hallucis brevis dorsally, exposing the long flexor tendons.
- Identify the FHL and flexor digitorum longus (FDL) tendons at the master knot of Henry (beware of the medial plantar nerve!) and cut the FHL tendon.
- The FHL stump can be tenodesed to the FDL tendon, but multiple communications exist between these two tendons and this is usually not necessary.
- Retract the FHL through the posterior calf incision.
- This technique allows the FHL tendon to be passed through a transverse bone tunnel in the posterior tuberosity of the calcaneus and looped back onto itself.
- The double strands of tendon are theoretically stronger than a single strand, but no advantage has been shown clinically with this technique.
- I prefer to use the first single-incision technique, limiting the risks of an additional incision and the risks to the structures dissected in the approach, including the medial plantar nerve and its branches.

**ACHILLES TENDON REPAIR**

- After the FHL transfer is completed, attention is moved back to the Achilles tendon.
- Oppose the proximal and distal ends of the tendon appropriately (via the V-Y slide) and tie them together with intratendinous knots, using the aforementioned nonabsorbable braided suture (TECH FIG 6A).
- Once again, confirm that the ankle resting tension remains equal to the contralateral side to avoid overtightening of the repair (TECH FIG 6B).
- Gently dorsiflex the ankle to ensure that no diastasis occurs between the tendon ends, confirming adequate integrity of the repair strength.
Suture the muscle belly of the FHL to the back of the Achilles tendon at the level of the repair with absorbable suture. This provides a vascular bed to the relatively disvascular level of the ruptured Achilles tendon, theoretically increasing the healing potential of the repair.

Repair the paratenon over the repaired Achilles tendon as a separate layer, using absorbable suture.

Close the skin in layers via routine closure.

Apply a well-padded posterior plaster splint with the ankle maintained at its resting level of plantarflexion (equal to the contralateral side), and release the tourniquet.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>As with any Achilles tendon surgery, wound edge necrosis remains a major risk factor. Patients need to be adequately assessed for vascularity, skin quality, and healing potential.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Surgical approach</td>
<td>The sural nerve may be trapped in scar tissue after the rupture and should be carefully dissected and protected.</td>
</tr>
<tr>
<td>V-Y lengthening</td>
<td>Ensure that adequate length is used for the limbs of the V. Twice the rupture gap length is recommended. Avoid excess traction of the proximal tendon, which may result in complete disruption of the myotendinous portion of the GSA complex.</td>
</tr>
<tr>
<td>FHL harvest</td>
<td>Beware of the deep neurovascular bundle immediately medial and adjacent to the FHL muscle and tendon at the distal tibial level. Dissect the FHL tendon to at least the level of the medial malleolus to ensure enough tendon length is available. When drilling the Beath pin, ensure that the ankle is dorsiflexed so that the bone tunnel direction is colinear with that of the Achilles tendon and the proposed tendon transfer. Ensure that adequate interference fit has been obtained with the screw in the bone tunnel by pulling on the tendon after insertion. Ensure that the FHL tendon is placed at adequate tension to match the unaffected side.</td>
</tr>
<tr>
<td>Closure</td>
<td>Care should be taken in repairing the paratenon. This has a rich vascular supply, which is important to the tendon repair, and aids in preventing adhesions to the tendon to the skin and subcutaneous tissue.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Postoperatively patients are splinted for 2 weeks in slight equinus (equal to the resting tension of the unaffected side).
- They are kept strictly non–weight-bearing for the first 6 postoperative weeks.
- At 2 weeks after surgery incisions are checked and sutures removed.
- Patients are placed into Achilles-type fracture boots (Bledsoe Inc., Grand Prairie, TX) with three heel wedges, and instructed to remove one wedge after 2 weeks.
- After 6 weeks patients are allowed to start bearing weight on the affected extremity as comfort allows in their protective Achilles boot braces (with two wedges in place at this point).

- Patients are then instructed to remove one wedge every 2 weeks thereafter.
- Physical therapy is performed two or three times a week for the subsequent 10 weeks and includes passive Achilles stretching, an Achilles strengthening program, and gait training. This is performed with the boot brace removed.
- Twelve weeks after surgery, if the ankle is in a neutral alignment, the boot brace is discontinued for ambulation, with the patient continuing the therapy program.
- Patients are instructed to slowly resume their activity as comfort allows, but to avoid sudden acceleration and cutting or jumping activities until at least 6 months after surgery.
OUTCOMES

- Outcomes of chronic or neglected Achilles tendon rupture repair are uniformly inferior to those of acute rupture repair.
- Using a V-Y advancement alone, Us et al\(^5\) reported up to 22% deficiency in peak torque compared to the unaffected side in 6 patients.
- Wapner et al\(^6\) reported on using the FHL tendon without V-Y advancement through a two-incision approach (with the second incision made in the medial longitudinal arch, where the FHL was harvested at the level of the master knot of Henry).
  - On Cybex testing they reported 29.5% average decrease in strength at 30°/s and decreases in torque and work generated by plantarflexion of the ankle as being 41.8% and 51% respectively compared to the nonoperated side.
  - In a recent study by Raikin et al\(^4\) using the combined V-Y lengthening and FHL augmentation described above on 15 patients with a minimum gap of 5 cm, a 7.7 N-m (−22.3%) loss of plantarflexion torque at 60°/s and a 3.5 N-m (−13.5%) loss of plantarflexion torque at 120°/s was seen on Cybex testing compared to the unaffected side.
  - Patients had an average 5-degree loss of active motion arc of the ankle joint in the sagittal plane. AOFAS ankle hind-foot scores improved from an average 58.4 out of 100 preoperatively to an average 94.1 out of 100 postoperatively.
  - Eight of 15 patients were able to perform more than 10 repetitions of a single-leg heel raise at 2-year follow-up.
  - All patients were satisfied with their outcome (rated good or very good).

COMPLICATIONS

- Wound edge necrosis
- Rerupture
- Plantarflexion weakness
- Sural neuritis or nerve injury
- Deep vein thrombosis

REFERENCES

DEFINITION
■ Rupture of the Achilles tendon is common.
■ More than 20% of acute injuries are misdiagnosed, leading to chronic or neglected ruptures.3
■ Most authors define chronic rupture as a rupture with a delay in diagnosis or treatment for more than 4 weeks.2,8,9

ANATOMY
■ The two heads of the gastrocnemius (medial and lateral) arise from the condyles of the femur, the fleshy part of the muscle extending to about the middle of the calf. As the muscle fibers descend they insert into a broad aponeurosis, which contracts and receives the tendon of the soleus on its deep surface to form the Achilles tendon.14
■ The Achilles tendon is the thickest and strongest tendon in the body. About 15 cm long, it originates in the middle of the calf and extends distally to insert into the posterior surface of the calcaneum. Throughout its length, it receives muscle fibers from the soleus on its anterior surface.14

PATHOGENESIS
■ The most common mechanism of injury is pushing off with the weight-bearing forefoot while extending the knee. However, sudden unexpected dorsiflexion of the ankle or violent dorsi-flexion of a plantarflexed foot may also result in ruptures.4
■ Corticosteroids, fluoroquinolones, previous tendon pathology, and poor vascularity of the Achilles tendon have been associated with rupture.4
■ Patients with chronic ruptures of the Achilles tendon recall either minimal trauma or an injury misdiagnosed as an ankle sprain. They commonly complain of a limp and difficulties with activities of daily living, particularly ascending stairs.5

PATIENT HISTORY AND PHYSICAL FINDINGS
■ Methods for examination include the following:
  ▪ Palpable gap. Gap is not always palpable in chronic ruptures.
  ▪ Calf squeeze test (Simmonds test or Thompson test)12: positive or negative. False positive may be possible if plantaris is present and intact.
  ▪ Knee flexion test (Matles test)6: A false positive may occur when there is neurologic weakness of the Achilles tendon.
  ▪ Patients may present with a limp.
  ▪ In acute tendon ruptures, a gap in the Achilles tendon is usually palpable. This gap may be absent in chronic ruptures, as the gap is usually bridged by scar tissue.
  ▪ Active plantarflexion of the foot is usually preserved due to the action of tibialis posterior, the peroneal tendons, and the long toe flexors.
  ▪ The calf squeeze test, first described by Simmonds in 1957,12 but often credited to Thompson, who redescribed it in 1962, is performed with the patient prone and ankles clear of the couch. The examiner squeezes the fleshy part of the calf, causing the deformation of the soleus and resulting in plantarflexion of the foot if the Achilles tendon is intact. The affected leg should be compared to the contralateral leg.
  ▪ The knee flexion test is performed with the patient prone and ankles clear of the table. The patient is asked to actively flex the knee to 90 degrees. During this movement the foot on the affected side falls into neutral or dorsiflexion and a rupture of the Achilles tendon can be diagnosed.6

IMAGING AND OTHER DIAGNOSTIC STUDIES
■ As clinical diagnosis of chronic ruptures can be problematic, imaging can be useful.
■ Plain lateral radiographs may reveal an irregular configuration of the fat-filled triangular space anterior to the Achilles tendon and between the posterior aspect of the tibia and superior aspect of the calcaneus (this space is known as the triangle of Kager).
■ Ultrasonography of a chronic rupture usually demonstrates an acoustic vacuum with thick irregular edges (FIG 1).
■ T1-weighted MR images will show disruption of signal within the tendon substance, while T2-weighted images show generalized high signal intensity.

DIFFERENTIAL DIAGNOSIS
■ Acute rupture of the Achilles tendon, rerupture of the Achilles tendon, tear of the musculotendinous junction of the gastrocnemius-soleus and the Achilles tendon.

NONOPERATIVE MANAGEMENT
■ Consensus is that the most appropriate treatment for chronic Achilles tendon ruptures is surgical.8

SURGICAL MANAGEMENT
■ A delay in presentation of Achilles tendon rupture results in filling of the gap between the ruptured tendon ends with fibrous nonfunctional scar, which needs excision. To re-establish tendon continuity, surgeons may consider the use of...
the following: (1) the residual Achilles tendon, (2) adjacent tendons, (3) autologous free tendon grafts, (4) allografts.

Preoperative Planning
- All imaging should be reviewed to estimate the tendon gap.
- If the gap in maximum plantarflexion is 5 to 9 cm, peroneus brevis transfer can be used.
- If the gap is 9 to 12 cm, we recommend a free autologous gracilis tendon graft.
- If these tendons have already been used for other reconstructive procedures, alternative surgical options will have to be considered.

Positioning
- Under general anesthesia, the patient is placed prone with the ankles clear of the operating table.
- A tourniquet is applied to the limb to be operated on. The limb is exsanguinated, and the tourniquet is inflated to 250 mm Hg.

Approach
- The traditional midline longitudinal approach over the Achilles tendon has been associated with wound healing problems and a risk of sural nerve injury when extended proximally.
- We do not use the lateral approach, given the high risk of sural nerve injury.
- We employ a 10- to 12-cm curvilinear approach medial to the medial border of the tendon with sharp dissection through the subcutaneous fat to the paratenon. This incision avoids the sural nerve.
- Maintaining thick skin flaps is vital to reduce the incidence of wound breakdown.

PERONEUS BREVIS TENDON TRANSFER FOR CHRONIC ACHILLES TENDON RUPTURE
- The Achilles tendon is exposed by longitudinal incision of the paratenon in the midline for the length of the skin incision.
- The ends of the Achilles tendon are freshened by sharp dissection, producing a defect between the freshened ends. The proximal stump is gently dissected out and mobilized distally (TECH FIG 1).
- Through the base of the wound, the deep fascia overlying the deep flexor compartment and the compartment containing the peronei muscles can be seen.
- The internervous plane lies between the peroneus brevis (supplied by the superficial peroneal nerve) and the flexor hallucis longus (supplied by the tibial nerve).
- The peroneus brevis tendon can be identified toward the medial side.
- The tendons of the peroneus longus and brevis can be distinguished from each other at this level by the fact that although both are tendinous in the distal third of the lower leg, the peroneus brevis is muscular more distally than the peroneus longus. The deep fascia overlying the peroneal tendons is incised and the peroneal tendons are mobilized.
- Make a 2.5-cm longitudinal incision over the base of the fifth metatarsal. Identify the peroneus brevis tendon, place a stay suture in the distal end of the peroneus brevis tendon, and detach the tendon from its insertion and mobilize it proximally.
- Deliver the tendon through the posteromedial wound using gentle continuous traction as it is pulled through the inferior peroneal retinaculum. In this fashion, the tendon of the peroneus brevis retains its blood supply from the intermuscular septum.
- Weave the peroneus brevis tendon through the Achilles tendon ends.

TECH FIG 1 • Repair of chronic Achilles tendon rupture with peroneus brevis. A. Tendon ends are débrided to demonstrate true defect. B. Proximal stump mobilized into wound. C. Incision made over insertion of peroneus brevis on the base of the fifth metatarsal. (continued)
First pass it from lateral to medial through the distal stump via coronal incisions medially and laterally in the Achilles tendon.

- Suture the edges of the coronal incisions in the Achilles tendon to the peroneus brevis tendon to prevent progression of the incision that would lead to the peroneal tendon cutting out through the Achilles tendon.

- Pass the tendon through the proximal stump from medial to lateral, with the foot maximally plantarflexed.

- Suture the peroneal tendon to the Achilles tendon stumps using 3-0 Vicryl. This is usually sufficient, but, if there is a very large defect, the tendon of the plantaris can be harvested, if present. This is then used to reinforce the reconstruction.

- In most cases of neglected ruptures of the Achilles tendon, the paratenon is either not present or not viable. If present, one can generally manage to close it over the proximal stump using 2-0 Vicryl.

- Close the skin with a continuous 2-0 subcuticular Vicryl suture. Steri-Strips are applied and the wound is dressed.

- The tourniquet is deflated and the time recorded.

---

**FREE GRACILIS TENDON GRAFT FOR CHRONIC RUPTURES OF THE ACHILLES TENDON**

- Make a 12- to 15-cm longitudinal, slightly curvilinear skin incision medial and anterior to the medial border of the Achilles tendon.

- The paratenon, if not disrupted, is incised longitudinally in the midline for the length of the skin incision.

- The Achilles tendon is thus exposed, and gentle continuous traction is applied to the proximal stump of the ruptured tendon to further deliver it into the wound (**TECH FIG 2**).

- Excise scar tissue in both the proximal and distal stumps to reach viable tendon.
If the remaining gap in the Achilles tendon is greater than 9 cm, we proceed to harvest the gracilis tendon.

Make a vertical 2- to 3-cm longitudinal incision on the medial aspect of the tibial tuberosity, centered over the distal insertion of the pes anserinus.

A venous plexus is often encountered at the distal end of the wound, and care should be taken to diathermy this.

Carry out dissection deep to the fat both medially and superiorly with a small swab on an artery forceps to expose the sartorius fascia.

Insert a curved retractor and make a curved incision, 1 cm long, along the superior margin of the pes anserinus into the sartorius fascia, taking care to avoid the saphenous nerve.

Use blunt dissection with Mackenrodt scissors to produce a window within the superior border of the sartorius allowing access to the tendon of gracilis.

The gracilis tendon lies more superiorly than the neighboring tendon of the semitendinosus and can be retrieved with a curved Moynihan clip.

As the tendon is brought into the wound, use of an arthroscopic probe helps to identify the possible tendon’s proximal vincular attachments. The vincula are sectioned to achieve distal traction on the tendon.

Before using a tendon stripper to harvest the tendon, all attachments to the tendon must be completely released. An assistant places his or her hand over the calf, and, by applying firm traction longitudinally, excludes the presence of remaining tendinous attachments by the absence of calf tethering.

Harvest the gracilis tendon with the tendon stripper by directing the instrument in line with the tendon fibers, parallel to the thigh.

Imaging can be useful in clinching the diagnosis and in preoperative planning. The tendon must be completely freed of its attachments before harvesting. Diagnosis is usually made on a clinical basis, but this can be difficult in cases of chronic rupture. For defects greater than 9 cm we recommend free gracilis graft. We recommend peroneus brevis transfer for Achilles tendon defects less than 9 cm.

A incision placed medial and anterior to the medial border of the Achilles tendon reduces the likelihood of sural nerve injury. Patients are encouraged to increase the frequency of their exercise. Cycling and swimming are started at 8 weeks postoperatively. Patients are allowed to return to their sport at the fifth postoperative month.

POSTOPERATIVE CARE

- Before the patient is taken off the operating table, a below-knee plaster-of-Paris cast is applied to the operated leg, with the patient prone and the ankle in maximal equinus.
- The operated leg is elevated until discharge.
- Patients are usually discharged on the day after surgery after having been taught to use crutches by an orthopaedic physiotherapist.
- Thromboprophylaxis is provided with Fragmin 2500 units (dalteparin sodium) subcutaneously once daily, or with 150 mg acetylsalicylic acid orally daily until removal of the cast.
- Patients are told to bear weight on the operated leg as able, but to keep it elevated as much as possible at home for the first 2 postoperative weeks.
- The cast is removed at the second postoperative week, and a synthetic anterior below-knee slab is applied with the foot in maximal equinus.
- The synthetic slab is secured to the leg with three or four removable Velcro straps for 4 weeks.
- Patients can graduate to full weight bearing as soon as comfort allows.
- A trained physiotherapist supervises the introduction of gentle mobilization exercises of the ankle, isometric contraction of the gastrocsoleus complex, and gentle concentric contraction of the calf muscles. Inversion and eversion of the ankle is also encouraged.
- At 6 weeks postoperatively, the patient is followed up and the anterior slab removed.
- Physiotherapists supervise gradual stretching and strengthening exercises.
- Patients are usually discharged on the day after surgery.

OUTCOMES

- We have reported on 22 patients with chronic Achilles tendon ruptures using peroneus brevis tendon transfer. All were satisfied with the procedure. Despite subjective patient satisfaction, however, objective evaluation demonstrated greater loss of isokinetic strength variables at high speeds, and greater loss of calf circumference when compared with patients undergoing open repair of fresh Achilles tendon ruptures. Gallant et al assessed eversion and plantarflexion strength after repair of Achilles tendon rupture using peroneus brevis tendon transfer and found mild objective eversion and plantar flexion weakness. However, subjective assessment revealed no functional compromise.
- In a study by Pintore et al, 21 patients treated with a free gracilis graft, 2 had excellent results, 15 had good results, and 4 had fair results. All returned to their preinjury occupation. Fifteen returned to leisure activities, including sports such as tennis, squash, and bowling.
- Maximum calf circumference was significantly decreased in the operated leg at both presentation and follow-up.
- The operated limb showed a lower peak torque than the nonoperated one, but patients did not perceive this as hampering their daily or leisure activities.

COMPLICATIONS

- Wound healing problems
- Infection
- Sural nerve injury
- Rerupture of Achilles tendon
- Deep vein thrombosis
REFERENCES

DEFINITION
- Chronic Achilles tendon ruptures are defined as those of greater than 3 months’ duration.
- There are three indications for this technique:
  - A defect between healthy ends of tendon of at least 5 cm. Procedures using local tissue or autograft tendon augmentation generally suffice for lesser defects.
  - An expectation of recovery of function that would not be provided by Achilles tendon direct repair or advancement or flexor hallucis longus transfer
  - Failed reconstruction using autologous tendon advancement or augmentation
- This technique may also be considered for patients with severe chronic Achilles tendinopathy that warrants resection of an extensive degenerated section of the tendon, leaving a gap similar to that observed in chronic Achilles tendon rupture.

ANATOMY
- The Achilles tendon is the condensation of the two heads of the gastrocnemius and soleus muscles. The musculotendinous junction is about 6 to 8 cm from its insertion into the central third of the posterior calcaneus.
- The enthesis is composed of cartilage and fibrocartilage, typically over an area of 6 cm². The posterior calcaneal tuberosity and retrotalar bursa lie anterosuperiorly.
- The tendon is surrounded by paratenon consisting of both parietal and visceral layers. These relatively pliable layers provide tendon blood supply, nutrition, and lubrication. The approximate physiologic excursion of the Achilles tendon is 1.5 cm.
- Blood supply, from vessels running the entire length of the paratenon, approach the tendon from its anterior surface via the mesotenon. The concentration and diameter of these vessels vary along the course of the paratenon, with the fewest being at the relatively hypovascular area 4 cm proximal to the insertion. The blood supply at the Achilles insertion on the calcaneus is also relatively avascular.¹

PATHOGENESIS
- Rupture occurs when the tendon is stressed beyond its yield point. The magnitude of this depends on the force and speed of loading, cross-sectional area of the tendon, and diminution of tendon quality by any pathologic process.
- Predisposing factors
  - Achilles tendinopathy
  - Corticosteroids (oral or locally infiltrated), anabolic steroids
  - Low normal level of exercise, aging
  - Gout, hyperthyroidism, renal insufficiency, arteriosclerosis
  - Fluoroquinolones
- Pathogenesis of tendinopathy and chronic tears
  - Chronic Achilles tendon tears most commonly occur with preexisting tendinopathy, tendinopathy that frequently was asymptomatic. Eighty percent of tears occur in the relatively hypovascular area 2 to 6 cm above the insertion; the second most common location for tendinopathy or chronic tears to develop is at the insertion on the calcaneus.
  - Tendinopathy is a result of microtrauma, hypovascularity, degeneration, and failure of healing. With progression, fibrovascular proliferation from the paratenon, accompanied by a marked lymphocytic and histiocytic response, develops in the degenerative tendon, leading to fibrinous and myxomatous degeneration of the Achilles tendon. These changes decrease the threshold for tendon rupture.
  - Pathologic changes in untreated ruptures
    - There is initial retraction of the tendon ends due to inherent muscle tension.
    - Within 2 weeks, fibrous organization of the tendon ends and hematoma occur.
    - There is a gradual transformation in shape of the tendon ends, with the distal and proximal portions respectively becoming more bulbous and conical. Moreover, the tendon ends tend to adhere to the investing fascia of the deep posterior compartment.
    - The hematoma in the gap between the tendon ends gradually organizes into fibrous scar tissue, which appears to reestablish tendon continuity but lacks contractile strength.
    - The fibroblasts remain disorganized rather than aligning in a physiologically correct longitudinal formation.
    - The resultant fibrous mass is rarely capable of withstanding the physiologic tensile forces of the gastrocnemius–soleus complex and thus develops further elongation and weakness.
- Rupture of the Achilles tendon may lead to (1) loss of plantarflexion power, (2) lack of control of the second rocker during the stance phase of gait, and (3) subjective and objective decrease in ankle stability.¹²,¹³

NATURAL HISTORY
- Most chronic ruptures present in older patients.
- Occasionally a prodrome of Achilles tendon symptoms is reported; however, there may have been only the typical palpable and visual changes that occur with tendinopathy.
- The patient will describe a sudden onset of pain of varying intensity either on stumbling (eccentric loading) or on push-off (concentric loading).
- The pain is usually associated with swelling and weakness, although if the tendon was previously dysfunctional due to tendinopathy, the difference may be small.
- Medical attention is often not sought because plantarflexion function, albeit weak, remains due to the contribution of the other ankle plantarflexors (flexor hallucis longus, flexor digitorum longus, peroneal tendons, and the posterior tibial tendon).
- The amount of disability with an untreated rupture is often determined by the patient’s premorbid status.
PATIENT HISTORY AND PHYSICAL FINDINGS

Physical examination methods include the following:

- Thompson–Simmond test: Abnormal result signifies a functional tear of Achilles tendon.
- Plantarflexion power: A score less than 4 indicates that a tear is likely; a score of 4 or 5 indicates that a tear is unlikely.
- Palpation of gap between tendon ends gives some indication of repair technique, should surgical reconstruction be considered.
- Gap in tendon: Mild = end-to-end repair; Moderate = V–Y advancement; severe = Achilles tendon allograft
- A complete history and physical examination should be done to determine associated injuries and predisposing factors.
- Inspection:
  - Gap in tendon
  - Calf atrophy
  - Resting tension of the foot with the patient prone and knee flexed, relative to the uninjured contralateral extremity
- Gait:
  - Antalgic
  - Vertical oscillation of pelvis with increased hip and knee flexion
  - Ankle instability
- Palpation of gap between tendon ends gives some indication of repair technique, should surgical reconstruction be considered.
  - 1 to 2 cm: usually end-to-end repair with or without tenodesis augmentation
  - 2 to 5 cm: usually V–Y advancement with or without tenodesis augmentation
  - More than 5 cm: autograft or allograft tendon transfer or reconstruction
- Range of motion: excessive dorsiflexion (FIG 1)
- Plantarflexion:
  - May still be present due to recruitment of tibialis posterior, flexor hallucis longus, flexor digitorum longus, and peroneal tendons
  - Decreased power
- Thompson–Simmond test
  - Premorbid conditions: skin quality, smoking, neurovascular status, diabetes mellitus

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Imaging studies for chronic Achilles tendon ruptures are typically not indicated.
- Plain radiographs may reveal calcification within the tendon, suggestive of a degenerative process leading to rupture.

NONOPERATIVE MANAGEMENT

- The extent of nonoperative treatment depends on level of symptoms and required level of functional improvement. Despite the seemingly devastating functional consequences of chronic Achilles tendon rupture, not all patients require a reconstructive procedure.

- Bracing:
  - The level of hindfoot and ankle stabilization required is determined by the power of plantarflexion power afforded by secondary muscles and to a lesser extent by the patient’s weight.
  - A relatively lightweight carbon-fiber ankle–foot orthosis (AFO) may enhance gait during push-off by transferring elastic recoil gained during dorsiflexion to plantarflexion to compensate for lack of Achilles tendon function. In our experience, this treatment is less suitable for heavier patients.
  - A clamshell AFO that encompasses the foot and ankle may be of greater benefit than a traditional AFO for patients with a combination of severe loss of plantarflexion function and poor ankle stability. The addition of an anterior component to the conventional AFO provides the advantage of resisting excessive ankle dorsiflexion.
  - In select patients, a double-upright brace attached to a stiffer-soled shoe and locked at the ankle may be as effective as a conventional or clamshell AFO.

- Physical therapy:
  - Physical therapy should focus on strengthening the secondary ankle plantarflexors (flexor hallucis longus, flexor digitorum longus, posterior tibial tendon, and peroneals)
  - Gait training, stabilization, and proprioception exercises

SURGICAL MANAGEMENT

- Advantages of allograft versus autograft:
  - No morbidity or loss of function and pain from donor site
  - Quality and amount of autogenous tendon may be insufficient
  - Shorter operative time as no harvesting is required
  - Satisfactory mechanical properties of allograft are proven

- Disadvantages:
  - Cost
  - Theoretical risk of transmission of host infectious diseases
Preoperative Planning
- Vascular status is assessed.
- The surgeon should ensure that the posterior lower leg skin is amenable to surgical intervention; if concern exists, the threshold for plastic surgery consultation should be low.
- The contralateral limb is assessed for natural resting tension of the gastrocnemius–soleus complex.
- Imaging studies, if obtained, may provide some understanding of the extent of degenerated Achilles tendon.

Positioning
- Before positioning, a well-padded tourniquet is applied. This should be on the thigh as to prevent tethering of the gastrocnemius–soleus complex and potential inaccuracies in allograft tensioning.
- We prefer a popliteal block for postoperative pain management in conjunction with general anesthesia to permit the patient to tolerate the thigh tourniquet. Depending on surgeon preference, a more proximal regional anesthetic, spinal, or epidural may be considered. The advantage to a popliteal block is improved leg function and potentially safer mobilization in the immediate postoperative period, since the proximal limb girdle muscle function is not forfeited.
- Prone positioning with adequate padding, maintenance of airway, avoidance of brachial plexus tension, and safe positioning of the patient’s genitalia are all important.

Approach
- A posterior approach to the distal lower leg is used with a midline incision of about 20 cm centered over the Achilles tendon and central posterior calcaneus. While this is our preferred technique, the surgical approach must respect prior surgical approaches to the Achilles tendon (FIG 2).

ALLOGRAFT RECONSTRUCTION OF CHRONIC ACHILLES TENDON RUPTURE
- The Achilles tendon allograft tissue, comprising the distal Achilles tendon with its insertion into a block of allograft calcaneus, is carefully inspected to ensure it has been properly screened, has not expired, and is appropriate for the proposed procedure.
- Make a longitudinal incision in the midline. If preexisting incisions are present, maintain a midline approach as best as possible while respecting the previous approach or approaches.
- Create full-thickness flaps and retract only the deeper tissues to minimize wound complications.
- Incise the tendon sheath longitudinally and reflect it.
- Define and mobilize the tendon ends.
- Débride the proximal tendon end, leaving only healthy tendon. With allograft Achilles tendon reconstruction, the distal Achilles tendon stump is resected completely (TECH FIG 1).
- Contour the block of allograft calcaneus attached to the Achilles allograft with a saw, rongeur, or both for insertion and fixation into the patient’s calcaneus.
- Use an oscillating saw to create a matching corticocancellous trough in the posterior aspect of the patient’s calcaneus. We prefer to use a flexible chisel to fine-tune this trough, which will accommodate the allograft bone (TECH FIG 2).
- After fully inserting the allograft’s bony portion into the patient’s calcaneal trough, secure the bony block using two fully threaded cancellous 4.0-mm titanium screws (DePuy ACE Screw System, Warsaw, IN) (TECH FIGS 3–5).
Insert a running nonabsorbable no. 2 whip suture (Ethibond, Ethicon, Somerville, NJ) on either side of the allograft tendon (TECH FIG 6).

By proximally tensioning the sutures, the ankle assumes a position of maximum equinus as the graft spans the defect. This tension is maintained until the allograft is adequately secured to the patient’s residual native Achilles tendon, with the no. 2 nonabsorbable suture being woven into the host tissue or secured to a symmetric no. 2 whip suture placed into the host tissue.

With healthy residual proximal host Achilles tendon, we recommend performing an end-to-end repair between allograft and host tendon. When the patient’s residual tendon is adequate but with suspect quality at the most distal portion of the host tissue, we routinely perform an overlapping, imbricated reconstruction.

Augment the repair or reconstruction with a running 2–0 Vicryl suture (Ethicon).

Close the paratenon with 4-0 Vicryl.

Reapproximate the subcutaneous layer with 4-0 Vicryl and close the skin with 4-0 nylon, while maintaining careful handling of the skin margins.

</table>
POSTOPERATIVE CARE

■ Immobilization in equinus in a bulky splint for 2 weeks
■ Suture removal at 2 weeks
■ Immobilization in a hinged cam walker (Bledsoe Platform Boot, Medical Technology Inc., Grand Prairie, TX) set to neutral dorsiflexion block and block at 20 degrees of plantarflexion. The foot is kept in equinus by inserting heel pads into the boot.
■ Partial weight bearing (25 kg) is commenced at 2 weeks. This is increased by increments of 25 kg per week until full weight bearing is achieved.
■ At 8 to 10 weeks the boot is swapped for a 1- to 2-cm heel raise inside a shoe.
■ Gentle passive and active range-of-motion exercises and isometric exercises are commenced at 4 weeks.
■ Gentle passive stretching is started at 4 weeks and effort is gradually increased until at 10 weeks, standing calf-stretching exercises are commenced.
■ Elastic band exercises are started upon removal of the boot. Stationary bike riding is started at 10 to 12 weeks, with gradual progression of exercise up to 18 weeks, when active push-off exercises are initiated.

OUTCOMES

■ In our hands, outcomes with this technique have been satisfactory and without wound complications (FIG 3).
■ Typically, at 20 weeks the patient can perform single-leg toe-raises and begin jogging and light sporting activities, if previously able (FIG 4).
■ In our experience, most patients return to their preoperative exercise level and return to their prior occupation.

COMPLICATIONS

■ Infection
■ Wound dehiscence
■ Rupture of repair
■ Incorrect tensioning
■ Aseptic necrosis of graft

REFERENCES

SURGICAL MANAGEMENT
- Indications include neglected ruptures requiring secondary repair or revision surgery.
- Soft tissue expansion over the Achilles tendon and subsequent repair of the tendon are performed as a staged, two-part procedure about 3 to 4 weeks apart.
- This can be particularly effective when performing augmented procedures that increase the girth at the distal tendon or when the local skin is contracted.

Preoperative Planning
- MRI studies are reviewed to determine the ideal placement of the expander and to plan second-stage repair.
- The patient is instructed on the rationale for the staged procedure and the importance of weekly follow-up visits between each stage.

IMPLANTATION OF EXPANDER
- The initial stage of treatment involves subcutaneous placement of a 70-mL, rectangular soft tissue expander (McGhan, Santa Barbara, CA) between the Achilles tendon and the skin (TECH FIG 1).
- After sterile preparation, make a longitudinal incision along the medial aspect of the ankle, adjacent to the course of the Achilles tendon.
- Perform superficial subcutaneous elevation until a pocket about 6 × 4 cm is created.
- Insert a McGhan tissue expander into this cavity and place the injection catheter away from the implant.
- Subcuticular closure is followed by reapproximation of the skin.
- 10 mL of normal saline is initially injected into the implant via the injection port.
- The patient is seen 1 week postoperatively for further inflation of the implant.
- Ten mL of normal saline is added to the expander weekly.

REMOVAL OF EXPANDER AND TENDON REPAIR
- The expander is removed 3 to 4 weeks postoperatively (TECH FIG 2). At that time, removal of the tissue expander and Achilles repair are performed.
- The previously created incision is accessed and extended as necessary. The expansion balloon is then easily removed from its subcutaneous pocket.
- Surgical repair of the injured tendon is carried out in the surgeon’s preferred fashion.

Positioning
- The prone position allows the best access when approaching the Achilles tendon.
- A well-padded pillow is placed underneath the knees and anterior tibia–ankle.
- This allows for free plantarflexion and dorsiflexion of the ankle.

Approach
- The preferred approach is a posteromedial incision adjacent to the Achilles tendon. This allows the surgeon to avoid injury to the short saphenous vein and sural nerve.
- Simple extension of the incision is performed for the second-stage definitive repair.
- The posteromedial incision may be extended into a lazy-S, L shape, or a direct medial approach.

TECH FIG 1 • McGhan 70-mL soft tissue expander.

TECH FIG 2 • Inflated soft tissue expander in place subcutaneously.
PEARLS AND PITFALLS

**Indications**
- This technique should be avoided in patients with diabetes, peripheral vascular disease, immunocompromise, or a history of tobacco use.

**Soft tissue expander inflation**
- Patients rarely tolerate more than 30 to 40 cc of total volume within the implant. The expansion rate may need adjustment (from 10 mL/week) depending on individual skin pliability.

POSTOPERATIVE CARE
- After the initial stage of insertion, the patient is followed weekly for subsequent expander inflation. The inflation rate is 10 mL per week for 3 to 4 weeks.
- After expander removal and second-stage reconstruction the operative limb is placed into a short-leg splint in 10 to 15 degrees of plantarflexion.
- Non-weight-bearing with immobilization in a short-leg cast is maintained for 3 weeks. Range-of-motion exercises are initiated at 3 to 4 weeks postoperatively. Finally, weight bearing is allowed at 6 weeks after surgical repair (FIG 1).

OUTCOMES
- This technique has been used successfully in our practice with no complications related directly to soft tissue expansion.

COMPICATIONS
- Infection
- Seroma
- Sural nerve injury
- Fibrotic reaction

REFERENCES
DEFINITION

- Patrick Haglund in 1928 described an enlarged posterior border of the os calcis.3
- This anatomy, Haglund deformity, becomes very important when external shoeing and repeated hyperdorsiflexion causes contact between the Achilles tendon, the retrocalcaneal bursa, and the posterior proximal border of the calcaneus.
- As a result, Haglund syndrome is commonly characterized by inflammation within the retrocalcaneal or Achilles tendon bursa and often secondarily presents as insertional Achilles tendinopathy.
- The posterior heel pain and swelling associated with Haglund syndrome is the result of mechanical irritation by the calcaneal prominence on the surrounding soft tissues and the Achilles tendon.
- After conservative measures have failed, Haglund deformity and retrocalcaneal bursitis can be treated surgically using either an open or an endoscopic technique.
- The endoscopic technique is an outpatient treatment that is associated with low morbidity and high outpatient satisfaction. There is a short recovery time and a short time to gain preprocedure activity level.
- Appropriate visualization of the Achilles tendon and removal of the calcaneal prominence and retrocalcaneal bursa can be effectively accomplished using an endoscopic technique.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Clinical evaluation may help differentiate between retrocalcaneal bursitis and Achilles tendinopathy, although the two often coexist.
- Pathology within the retrocalcaneal space is detected on clinical examination with point tenderness along the anteromedial and anterolateral aspects of the Achilles tendon and an associated prominence of the calcaneus.
- Palpation of the affected hindfoot often reveals tenderness at the distal portion of the Achilles tendon proximal to its insertion on the calcaneus. The pain can be reproduced with passive or active dorsiflexion.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Imaging can assist with documenting the presence or absence of tendinopathy (FIG 1A).
- It can be difficult to distinguish whether symptoms are caused by retrocalcaneal bursitis or insertional Achilles tendinitis or tenosynovitis, and the two conditions often coexist.
- MRI can be used preoperatively to better demonstrate the coexistence of the two diagnoses (FIG 1B).
- Normal-appearing and diseased tendons can be distinguished endoscopically.

NONOPERATIVE MANAGEMENT

- Nonoperative measures for the treatment of posterior heel pain include the use of nonsteroidal anti-inflammatory medication, shoe wear modification (such as avoiding backless shoes), physical therapy for icing, other modalities, stretching exercises, pressure-release inserts, and hands-on friction massage.
- Local injections can be given in the retrocalcaneal space, but the concomitant use of local anesthesia and corticosteroids may further weaken the substance of the Achilles tendon and risk weakness and further micro- or macro-rupture of the tendon.4

PATHOGENESIS

- The retrocalcaneal space has been described as a disc space bursa covering the posterior superior angle of the calcaneus.2 The bursa walls may become diseased and hypertrophied with repeat hindfoot movement.
- Achilles tendinopathy is a degenerative process within the tendon substance causing microtears, edema, and reactive fibrosis with scar formation. These changes cause secondary mechanical irritation of the surrounding tissues and can even stimulate an inflammatory process.
SURGICAL MANAGEMENT

- The goal of treatment of Haglund deformity and syndrome is to remove the calcaneal prominence and to decompress the inflamed surrounding soft tissues.
- Open surgical correction is an alternative for patients who have failed to respond to nonoperative measures, especially if augmentation is advisable.
- Open procedures include resection of the calcaneal prominence proximal to the Achilles tendon insertion with retrocalcaneal bursa removal.
- A dorsal closing wedge osteotomy can rotate the posterior calcaneus to less prominence.
- Achilles tenolysis and partial resection of the diseased portion of the tendon may be necessary, often with augmentation by the flexor hallucis longus or flexor digitorum.
- Complete Achilles removal at its insertion is occasionally necessary.
- Complications associated with these procedures include hematomas, tendon or skin breakdown, nonunion, Achilles tendon avulsion, tenderness around the operative scar, cosmetic problems, altered sensation around the heel, and stiffness. Rehabilitation can be prolonged.
- The endoscopic technique of decompressing the retrocalcaneal space was developed to reduce morbidity and decrease the functional time to recovery for patients with retrocalcaneal bursitis.

Positioning

- The operation is performed with the patient in the supine position and under either general or regional anesthesia.
- A high thigh tourniquet is inflated to 300 mm Hg after Esmarch ischemia.
- The foot is positioned at the edge of the operating table. This enables the surgeon to place the foot against his or her body while using both hands to operate the arthroscopic instruments.
- The leg rests on a firm padded 12-inch-long and 4-inch-diameter cylindrical bump that allows the surgeon ample room to work and to control ankle dorsiflexion and plantarflexion.
- Alternatively, the prone position can be used.
- Both positions allow the patient’s foot to be controlled against the chest of the surgeon, who can then have both hands free for the instruments.

PORTAL PLACEMENT AND EXPOSURE

- Make a lateral portal through a vertical incision at the level of the superior aspect of the calcaneus (TECH FIG 1A).
- The incision is slightly anterior to the Achilles tendon and posterior to the sural nerve. It is important to bluntly dissect and spread the soft tissues when making the lateral portal to minimize the risk of injury to the sural nerve.
- Enter the retrocalcaneal space with a blunt trocar to develop working space.
- Place a 4.0-mm arthroscope into the retrocalcaneal space.
- Establish the medial portal similarly just anterior to the Achilles tendon, using the light of the arthroscope as a guide (TECH FIG 1B).

RESECTION AND DECOMPRESSION

- Introduce a 3.5-mm arthroscopic shaver (for larger hindfeet, a 4.5-mm arthroscope can be used) into the medial portal and remove the bursal tissue. This expanded working space creates visualization and access to the posterior calcaneus and the Achilles tendon attachment.
Depending on the quality of the bone, use either the arthroscopic shaver or a 4-mm arthroscopic burr to resect the posterior superior calcaneal prominence (TECH FIG 2).

- Keep the hooded portions of the instruments toward the anterior direction.
- Take special care to stop the rotating or oscillating shaver or burr usage when the instrumentation enters or exits the portal.
- Carry out the resection both medially and laterally into the sulcus of the calcaneal tendon (retrocalcaneal bursa) and distally to the attachment of the Achilles tendon.
- Visually confirm adequate exposure and resection of the osseous prominence until there are no areas of Achilles tendon impingement.
  - In a few cases, the use of the mini C-arm (Mini 6600 series; GE OEC Medical Systems, Salt Lake City, UT) is needed to determine, document, and confirm adequate resection.
- Damaged or diseased Achilles tendon can be selectively exposed and with a nerve hook or probe identified.
- Limited bone or tendinopathy can be removed with the arthroscopic shaver.
- An 18-gauge needle can be inserted several times into the tendon to promote blood ingress and collagen scar where there is myxoid or degenerative change.
- The rationale for this is to initiate a vascular response within the tendons for healing; it is performed with or without débridement.
- Insert an arthroscopic probe into the retrocalcaneal space to confirm continuing effective attachment of the Achilles tendon.

**COMPLETION AND WOUND CLOSURE**

- Hyper-plantarflex and dorsiflex the foot with the anterior chest and abdomen to verify any last areas of impingement.
- Irrigate and suction the retrocalcaneal space to remove any loose tissue.
- Close the portal sites with two 4-0 nylon skin horizontal mattress sutures.
- Inject local anesthetic (0.25% Marcaine without epinephrine) into the portal sites.
- Apply a compression dressing and splint the foot into slight equinus with the posterior splint and sugar-tong "trilaminar splint."

**PEARLS AND PITFALLS**

- Set up with heels directly at the end of operating room table so can manage position of ankle/foot in dorsiflexion and plantarflexion with chest/abdomen.
- Develop entire operative field from posteromedial to posterolateral corner so panoramic view of Achilles tuberosity attachment.
- MRI is necessary preoperatively to document insertional tendinopathy. If more than 25% of the cross-sectional area of the tendon is involved, open repair may be necessary (author’s opinion).
- Experience enables removal of paratenon and further removal of small ruptures and/or ossification in selected cases and situations.
- Postoperative routine is (a) non-weight-bearing for 2 to 3 weeks, (b) partial weight-bearing for 2 to 3 weeks, and (c) to maximize strength of posterior tibial and peroneals as soon as mobilization permits.
POSTOPERATIVE CARE
- The average time until full weight bearing is 4 weeks.
- Patients wear shoes with a heel counter and return to normal daily function in 8 weeks.
- All athletes returned to their previous level of activity in an average of 12 weeks.
- Patients may need a longer period of cast immobilization after débridement of the Achilles tendon or significant Achilles tendinopathy.

OUTCOMES
- In our study of endoscopic bony and soft tissue decompression of the retrocalcaneal space for the treatment of Haglund deformity and retrocalcaneal bursitis,9 32 heels in 30 consecutive patients underwent endoscopic decompression. The time of surgery after diagnosis of retrocalcaneal bursitis averaged 20 months. All patients had failed to respond to nonoperative measures, and none had undergone previous surgery.
- Indications for operative intervention included failed nonoperative measures, history and physical examinations consistent with retrocalcaneal bursitis, and Haglund deformity causing mechanical impingement or Achilles tendinopathy.
- Patients were prospectively followed from 1997 to 2003, with a mean follow-up of 35 months (range 3 to 62 months).
- Thirty heels completed subjective and objective measures using the American Orthopaedic Foot and Ankle Society (AOFAS) ankle–hindfoot scale.5
  - Twenty-eight patients had an average preoperative AOFAS score of 62 points. Postoperative AOFAS scores averaged 97 points.
  - Twenty-six patients had excellent results and three had good results. There was one poor result and one major complication. An excellent result was defined as pain-free activity with complete return to activity, and a poor result was defined as having persistent symptoms and inability to return to activity.
  - The cohort was stratified into “daily athletic activity” and “athletic” groups and the groups were compared. No statistical differences in outcome between the two groups existed.
  - All patients reported satisfaction with the cosmetic appearance of their portal sites.
- These results compared with those published by van Dijk et al13: their 20 patients resumed participating in sports at an average of 12 weeks.

COMPLICATIONS
- One major complication occurred among the 30 heels: a patient sustained a proximal Achilles tendon rupture (of an unprotected tendon) 19 days after having undergone endoscopic decompression while ambulating without a prescribed protected walker boot.9
- There were no intraoperative or skin or soft tissue complications (ie, wound dehiscence and postoperative infection).
- No patients reported a painful scar or neuroma-type symptoms.

REFERENCES
DEFINITION
- Insertional Achilles tendinopathy is posterior heel pain at the insertion of the Achilles tendon.
- The clinical diagnosis is acute and chronic pathology of the Achilles tendon insertion and its surrounding tissues.

ANATOMY
- The Achilles tendon, the condensation of the gastrocnemius and soleus tendons, inserts on the posterior calcaneal tuberosity.
- The insertion is not only posterior but also on the medial and lateral aspects of the calcaneus.
- A dorsal-posterior calcaneal prominence is most obvious on a lateral radiograph. The Achilles tendon inserts distal to this, directly posterior on the calcaneus.
- Between the distal Achilles tendon and the dorsal-posterior calcaneal prominence, immediately proximal to the Achilles insertion, is the retrocalcaneal bursa.
- A pre-Achilles bursa is superficial to the distal Achilles tendon.

PATHOGENESIS
- While not fully understood, repetitive microtrauma to the Achilles tendon insertion is thought to be the cause.
- Most likely some initial injury occurs, followed by multiple minor reinjuries that lead to chronic symptoms.
- In the acute phase, the process may have some inflammatory characteristics; however, the chronic process is degenerative, with a relative paucity of inflammatory tissue.
- Without histologic confirmation, the diagnosis of Achilles tendinitis or tendinosis cannot be made; therefore, the pathologic process at the Achilles tendon insertion is viewed as “tendinopathy” without tissue confirmation.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The patient may recall an inciting event but typically reports chronic activity-related aching or even sharp pain at the posterior heel.
- In addition, the patient notes a progressively enlarging prominence on the posterior heel.
- This ache is usually accompanied by exquisite tenderness directly posteriorly on the calcaneus, at the Achilles tendon insertion, with manual pressure, on contact from the shoe’s heel counter, or when the posterior heel is rested on a hard surface.
- Putting the Achilles tendon on stretch aggravates the symptoms, such as when the patient walks uphill.
- Physical examination reveals the following:
  - A prominence is evident on the posterior heel, at the Achilles tendon insertion (FIG 1).
  - Tenderness is felt directly on the posterior calcaneal prominence.
  - No tenderness is found in the Achilles tendon proximal to its insertion on the calcaneus.
  - Thompson’s test is negative.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- A lateral weight-bearing radiograph of the foot often demonstrates irregularities and calcifications at the Achilles tendon insertion on the posterior calcaneus (FIG 2A).
- While unnecessary to make the diagnosis, magnetic resonance imaging (MRI) defines the extent of tendon involvement at the insertion and the presence of retrocalcaneal and perhaps even pre-Achilles bursitis (FIG 2B).

DIFFERENTIAL DIAGNOSIS
- Pre-Achilles bursitis
- Retrocalcaneal bursitis
- Calcaneal stress fracture
- Haglund’s deformity (prominent dorsal-posterior calcaneal tuberosity impinging on the Achilles tendon)
- Calcaneal stress fracture
- Posterior ankle impingement
- Plantar fasciitis
- Noninsertional Achilles tendinopathy

NONOPERATIVE MANAGEMENT
- Activity modification (avoidance of activities that place the Achilles tendon on stretch)
- Nonsteroidal anti-inflammatory agents
- Heel lift or a shoe with a heel to unload the Achilles tendon
- Open-backed shoe or a shoe with a soft heel counter

FIG 1 • Example of posterior calcaneal prominence characteristic of insertional Achilles tendinopathy.
Physical therapy
- Focus on eccentric strengthening exercises
- In our experience the common practice of aggressive Achilles stretching must be avoided as it will aggravate the symptoms.
- Modalities: ultrasound, iontophoresis
- Extracorporeal shockwave therapy may have some benefit but is largely unproven.
- Corticosteroid injection may lead to Achilles rupture and is contraindicated unless the process is isolated to retrocalcaneal bursitis, in which case a judicious injection of only the retrocalcaneal bursa can be performed.

SURGICAL MANAGEMENT
- The primary surgical indication is nonoperative management.
- Up to 50% of insertional Achilles tendinopathy can be successfully managed without surgery, even when there is a large posterior calcaneal prominence.
- Insertional Achilles tendinopathy with central calcific tendinosis may be less amenable to nonoperative management.

Preoperative Planning
- Preoperative medical clearance
- Even in healthy patients, the thin skin on the posterior heel is at risk. Carefully inspect skin to be sure that the patient is a reasonable candidate for a posterior approach to the Achilles tendon insertion.
- With extensive Achilles tendon degeneration (confirmed with preoperative MRI), an augmentation of the insertion may be warranted. Therefore, preoperative planning should include the anticipation that the flexor hallucis longus (FHL) tendon may need to be harvested and transferred to the posterior calcaneus. The FHL tendon lies immediately deep to the deep compartment fascia that is anterior to the Achilles tendon and can readily be harvested through the same approach.
- As a rough estimate, we perform an FHL augmentation in less than 10% of cases but routinely have our preferred anchoring system available should the transfer be warranted.
- We educate all of our patients undergoing surgical management for insertional Achilles tendinopathy that, based on our intraoperative findings, an FHL tendon transfer may be necessary.
- The recovery following surgical management for insertional Achilles tendinopathy is prolonged and may take a full year before the patient returns to full activity. We educate our patients that the recovery is not rapid.

Positioning
- The patient is placed prone on the operating table.
- We routinely inflate the thigh tourniquet with the patient supine on the stretcher, then flip the patient to the prone position on the operating room table. This facilitates proper tourniquet position and avoids stressing the patient’s lumbar spine, which may be stressed when placing the tourniquet with the patient in the prone position.
- The chest and pelvis are well padded.
- The brachial plexi and ulnar nerves at the elbows are protected and relaxed.
- The genitalia are protected.

APPROACH AND REFLECTION OF THE ACHILLES TENDON INSERTION
- A central approach is undertaken, directly over Achilles tendon and posterior calcaneus (TECH FIG 1A).
- The scalpel is moved through skin and into central portion of distal Achilles tendon. Deep incision is continued distally, directly to bone.
- The goal is to avoid unnecessary delamination of the soft tissues and to elevate full-thickness flaps.
- We then elevate medial and lateral slips of Achilles tendon from the calcaneus (TECH FIG 1B,C).
- More than half of the Achilles tendon insertion can be elevated without compromising the integrity of the insertion. One study suggests that up to 75% can be released.
- We elevate the Achilles tendon until all the diseased portion of tendon can be excised.
Another study suggests that the entire insertion of the Achilles tendon should be routinely elevated and excised to ensure that all diseased tissue is removed. Reattachment is facilitated by a proximal Achilles tendon lengthening that also serves to unload the Achilles tendon.

We do not routinely elevate the entire Achilles tendon, but should one or both of the Achilles tendon slips become detached, we have uniformly been able to reattach the tendon to the calcaneus with a successful outcome.

**DÉBRIDEMENT OF THE DISEASED PORTION OF ACHILLES TENDON**

- The diseased portion of tendon is gradually pared from the Achilles insertion, until only healthy fibers remain (**TECH FIG 2A–C**).
- Healthy Achilles fibers have an organized, longitudinal pattern.
- Degenerated Achilles tendon substance is unorganized and may be likened to crab meat (**TECH FIG 2D,E**).
- Calcific tendinosis may be present, and all calcifications within the residual Achilles tendon must be excised (**TECH FIG 2F**).
CALCANEAL EXOSTECTOMY

- Retractors are used to protect the medial and lateral Achilles tendon slips.
- We routinely use a microsagittal saw to perform the exostectomy.
- We first define the exit point on the dorsal calcaneus in order to avoid the tendency to take unnecessary calcaneal bone (TECH FIG 3A).
  - If necessary, a single fluoroscopy spot image may be used to define the trajectory of the saw blade.
  - As a general rule, it is steeper (more vertical) than anticipated (TECH FIG 3B).
- The bony prominence is mobilized with a chisel and removed with a rongeur (TECH FIG 3C,D).
- Commonly, the exostectomy must be “touched up” to remove all of the prominence (TECH FIG 3E).
- With the Achilles tendon slips still protected, the medial and lateral chamfers are removed (TECH FIG 3F,G).
- This helps narrow the heel and reduce the bulk of the residual calcaneus, medial, and lateral prominences that may lead to persistent pressure and impingement experienced by the patient.
- While these chamfers are near the medial and lateral insertion points of the Achilles tendon, typically they can be excised without compromising the residual tendon attachment.
TECH FIG 3 • (continued) D. A rongeur is used to remove the resected bone. E. Touch-up to ensure an appropriate amount of bone was removed and an adequate “healing” cancellous surface is exposed. Chamfer preparation to decompress the lateral (F) and medial (G) dimensions of the prominent calcaneus.

REATTACHMENT OF RESIDUAL HEALTHY ACHILLES TENDON

Primary Sutures

- With only healthy Achilles tendon fibers remaining and the calcaneus decompressed posteriorly, medially, and laterally, the Achilles tendon should be reattached to the calcaneus.
- While one study suggested that up to 75% of the tendon attachment can be released without compromising the integrity of the insertion, we routinely reattach the elevated portion of tendon to the exposed cancellous calcaneal surface.
- In our opinion, reattachment not only strengthens the repair but also facilitates direct tendon healing to the calcaneus.
- We routinely use two or three suture anchors:
  - One anchor for each tendon slip
  - Occasionally, an additional anchor to augment the reattachment of both tendon slips
- The anchors are positioned relatively symmetrically on the exposed cancellous surface, in a position that will allow for each respective tendon slip to be reapproximated to the calcaneus in a balanced fashion (TECH FIG 4A,B).
- The anchors must be strong enough to lift the foot from the bed (TECH FIG 4C–E). If they should fail, we would prefer for them to fail now so we can rectify the problem.

TECH FIG 4 • A. Anchor being started into bone. B. Anchor secured to bone. (continued)
Balancing and Securing the Sutures

- The anchor sutures are then passed in through their respective tendon slip, also in a balanced manner to ensure that the tendon slips have near equal tension once the sutures are secured (TECH FIG 5A–C).
- We routinely check the anticipated tension by pushing the tendon slip to bone while tensioning the sutures after they have been passed through the tendon.
- If the tension does not appear to be equal in the two slips, we readjust the position of the sutures.
- The sutures must not only be tensioned appropriately in the longitudinal plane but must also be balanced well in the medial-to-lateral plane, so that the two tendon slips may also be reapproximated side to side and reconfigure the physiologic Achilles attachment.
- The sutures are then secured (TECH FIG 5D,E). Have the assistant hold the ankle in plantarflexion so that the tendon slips fully contact the calcaneus.
Additional Sutures

- We have a low threshold to place a third suture anchor to further stabilize both Achilles slips distally on the calcaneus (TECH FIG 6A–C).
- Finally, the most distal Achilles fibers are reapproximated to the fascial tissue immediately distal to the calcaneus (TECH FIG 6D,E).
- Avoid trapping fat in this portion of the repair as it may lead to fat necrosis.
- The two Achilles slips are then reapproximated to one another with an absorbable suture (TECH FIG 6F).
- Gently test dorsiflexion. The ankle should typically still reach neutral without compromising the repair. If it does not, however, it is not a problem.
- Patients rarely if ever develop equinus contracture.
- Once the Achilles tendon insertion is again healthy and asymptomatic, it has been our experience that the gastrocnemius and soleus muscles accommodate.
FOOT AND ANKLE • Section V  SPORTS-RELATED PROCEDURES FOR ANKLE AND HINDFOOT

TECH FIG 6 • (continued) F. Reapproximating two tendon slips proximal to the reattachment.

CLOSURE

- Close the paratenon (TECH FIG 7A).
- Reapproximate the subcutaneous tissues (TECH FIG 7B).
- Perform a tensionless closure. We routinely use staples in the proximal wound but favor suture in the distal wound, where the skin does not evert as readily (TECH FIG 7C).
- Sterile dressings, abundant padding, and a posterior splint with the ankle in its resting tension complete the closure.

TECH FIG 7 • Closure. A. Paratenon. B. Subcutaneous tissue. C. Skin (sutures are used distally to ensure that skin margins did not invert).

FLEXOR HALLUCIS TENDON AUGMENTATION

- Only rare patients present with a combination of insertional and noninsertional Achilles tendinopathy.
- Extensive débridement of diseased tendon is required (TECH FIG 8A,B).
- After fasciotomy of the deep compartment, the FHL tendon is identified, the tibial nerve is protected, and the FHL is harvested from its medial fibroosseous tunnel with the ankle and hallux interphalangeal joint in maximum plantarflexion (TECH FIG 8C).
- With this local (short) harvest of the FHL, in contrast to a long harvest from the plantar foot via a separate incision, the tendon length is ample for augmentation of the Achilles reattachment (TECH FIG 8D).
- The FHL tendon is anchored via an interference screw in the central calcaneus, within the exposed cancellous surface created after exostectomy (TECH FIG 8E).
- A suture goes through the plantar calcaneus to allow optimal tensioning of the FHL tendon (TECH FIG 8F).
- Suture anchors for reattachment of the Achilles slips are balanced on either side of the FHL anchor point (TECH FIG 8G).
**PEARLS AND PITFALLS**

</table>
| Reattachment of the healthy Achilles tendon to the calcaneus | The two Achilles tendon slips should be reattached in a balanced manner on the exposed cancellous surface of the calcaneus.  
Before tying the sutures of the suture anchors, check that the tension appears nearly equal for the two tendon slips. |
| Paratenon                        | As for repair of acute Achilles tendon ruptures, be sure to close the paratenon over the tendon. |
| FHL tendon augmentation          | This is an intraoperative decision and, in our experience, rarely necessary. If augmentation is needed, perform an FHL harvest through the same incision via a deep compartment fasciotomy. Be sure to identify and protect the tibial nerve that will be immediately adjacent to the FHL tendon. Transfer the tendon as far posteriorly on the exposed cancellous surface of the calcaneus as possible for the greatest mechanical advantage. |
POSTOPERATIVE CARE

■ Weeks 0 to 2: Posterior splint with the ankle in resting tension of plantarflexion
■ At 2 weeks: Return to clinic for suture removal and casting
■ Weeks 2 to 5: Short leg, plantarflexed (5 to 10 degrees) weight-bearing cast, with weight bearing permitted but use of an assistive device encouraged
■ At 5 weeks: Return to clinic for cast removal and transfer to a cam boot
■ Weeks 5 to 8: Cam walker boot with a 5- to 10-degree heel lift; initiate a physical therapy program, with a gradual progression to careful resistance exercises
■ Weeks 8 to 12: Progression to a regular shoe with a heel lift or an open-back shoe with a slight heel; physical therapy with a progressive eccentric strengthening exercises
■ Between 3 and 6 months: return to full activities; home program for physical therapy
■ It may take a full year before patients “can forget about this Achilles tendon.”
■ Maintain independent basic physical therapy exercises for a lifetime.

OUTCOMES

■ Most patients undergoing surgical management of insertional Achilles tendinopathy have good to excellent results, albeit without returning to full activity for 6 to 12 months.
■ However, most studies note that there are patients that do not return to full activity and while they are improved, they are not pain-free.
■ Johnson et al5 reported a mean improvement in the AOFAS ankle outcomes score from 53 to 89 points for 22 patients at 34 months’ average follow-up.
■ McGarvey et al9 noted an 82% satisfaction rate in 22 patients at mean follow-up of 33 months. Thirteen of 22 patients were pain-free and and an equal number could return to full activities.

COMPLICATIONS

■ Wound dehiscence
■ Infection
■ Avulsion of Achilles tendon from anchors on calcaneus
■ Persistent pain despite apparent successful procedure
■ Suture reaction or irritation

REFERENCES

DEFINITION
- Calcific Achilles tendinopathy is the most common cause of posterior heel pain.
- Intratendinous degeneration results in ectopic calcification and ossification at the Achilles tendon insertion to the calcaneus.

ANATOMY
- The Achilles tendon inserts over the inferior half of the posterior calcaneal tuberosity (FIG 1).
- The insertion expands over the tuberosity to become the calcaneal periosteum.
- The inferior half of the posterior calcaneal tuberosity has a rough surface with an extensive Sharpey fiber network.
- The superior half of the posterior calcaneal tuberosity has a smooth, almost articular surface.
- The retrocalcaneal bursa occupies the interval between the Achilles tendon and the superior half of the posterior calcaneal tuberosity. The bursa also extends superiorly over the posterosuperior process of the calcaneus.
- The ossification–calcification typically develops at the insertion, extends proximally into the tendon, and may comprise several segments within the more proximal tendon.

PATHOGENESIS
- The pathogenesis is not well understood.
- Two patient groups are typically affected: athletically active individuals in their 30s and 40s and overweight women in their 50s and 60s.
- Biochemical and histologic findings include:
  - Degenerative changes
  - An anaerobic environment
  - Longitudinal tears of the Achilles tendon
  - Chondral metaplasia and endochondral ossification without insertional fibers from the tendon
- Peritendinous swelling is rare, but increased caliber of the Achilles tendon may be present.
- Weakness is rare, but Achilles tendon contracture is common.
- Achilles tightness should be addressed with stretching before considering nonoperative treatment a failure.
- Pain with resisted plantarflexion suggests more extensive tendinosis.

NATURAL HISTORY
- Symptoms compromise the patient’s ability to wear shoes with a heel counter and participate in activity ranging from walking to intense athletic activity.
- Symptoms may improve in at least 50% of cases with activity modification, physical therapy, or shoe modifications.
- Disabling symptoms that do not improve with nonoperative treatment may benefit from surgery.
- Achilles tendon rupture in the presence of insertional calcification is extremely rare, even without any form of treatment.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The typical patient complaint is posterior heel pain aggravated by activity or shoe wear.
- Symptoms develop insidiously over time.
- Inflammatory enthesopathies such as psoriasis, Reiter syndrome, and inflammatory bowel disease may be present.
- Tenderness localized to the Achilles insertion on palpation (the examiner should press directly posteriorly on the heel where the Achilles tendon inserts) confirms the diagnosis.
- Tenderness may also be present in the Achilles tendon itself or over the retrocalcaneal bursa. The examiner should lightly squeeze the tendon between the index finger and thumb; squeezing hard on the tendon can result in a false-positive result. A thickened or painful tendon will require MRI to determine whether tendon transfer reconstruction is necessary.

FIG 1 • Anatomy of insertional calcification of the Achilles tendon. Note expansion of Achilles tendon fibers over posterior calcaneal tuberosity and intratendinous location of calcification.
Pain with maximum passive plantarflexion suggests inflammation of the paratenon.

Palpation of the retrocalcaneal bursa will differentiate retrocalcaneal bursitis from insertional tendinosis because a tender retrocalcaneal bursa may benefit from bursectomy.

Pain with toe walking supports the diagnosis. Inability to do either suggests the need for rehabilitation before considering surgery.

The surgeon must accurately assess the neurovascular status of the foot and the presence and appearance of any previous incisional scars.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Lateral radiograph of heel (FIG 2)
  - The examiner should identify insertional ossification, characterize the size of the posterosuperior process of the calcaneus, and identify intratendinous calcification more proximally.
  - Parallel pitch lines and the Fowler angle provide no diagnostic, therapeutic, or prognostic information.
  - MRI is indicated when the tendon is thickened, tender, or calcified to determine whether greater than 50% of the cross-sectional area of the tendon is involved (FIG 3).

**DIFFERENTIAL DIAGNOSIS**

- Retrocalcaneal bursitis
- Calcaneal stress fracture
- Plantar fasciitis
- Calcaneal periostitis
- Achilles tendinosis without insertional calcification

**NONOPERATIVE MANAGEMENT**

- Nonoperative management is helpful in at least 50% of cases.
- Initial treatment is with a removable walker boot with removable wedges.
- Two or three wedges are used for 2 weeks, and then a wedge is removed every 2 weeks.
- Use of the boot is continued for 2 weeks after removal of the last wedge.
- Weight bearing as tolerated is permitted in the boot.

- Physical therapy is started upon completion of removable walker boot immobilization and should include eccentric closed-chain strengthening exercises.\(^6\)
- Corticosteroid injection is contraindicated.

**SURGICAL MANAGEMENT**

- Surgical treatment is indicated for disabling symptoms that do not improve with thorough nonoperative treatment.
- Patients should be counseled that recovery can be a lengthy and sometimes frustrating process, as it is often 12 to 18 months before maximum improvement occurs, especially in nonathletic patients.\(^4\,7\)
- Recurrent prominence occurs in 50% of cases but is rarely symptomatic.\(^7\)

**Preoperative Planning**

- It may be helpful to have patients undergo crutch training preoperatively.
- A flexor hallucis longus tendon transfer reconstruction of the Achilles tendon will be necessary if an MRI demonstrates that greater than 50% of the cross-sectional area of the Achilles tendon is involved with degenerative tendinosis.

**Positioning**

- The lateral or prone position is necessary. The heel is more accessible in older or heavier patients when positioned prone. Anesthesia concerns may require lateral positioning.

**Approach**

- Lateral, medial, posterior, and combined approaches have all been described. The lateral approach will be described here.
- Advantages of the lateral approach are:
  - Direct exposure of the insertional calcification
  - Less compromise of the Achilles insertion expansion than other approaches because the strongest insertion is medial
  - The scar is less likely to be irritated by shoes, as with the posterior approach.

**FIG 2 • Lateral radiograph of heel with insertional calcification of the Achilles tendon.**

**FIG 3 • Axial T1-weighted MRI showing intratendinous degeneration comprising greater than 50% of the cross-sectional area of the Achilles tendon (white arrow).**
After administration of anesthesia, position the patient lateral decubitus or prone.
- Apply a thigh tourniquet.
- Prepare and drape the leg, exsanguinate the leg, and inflate the tourniquet.
- Make a longitudinal incision along the lateral heel anterior to the anterior margin of the Achilles tendon. The incision should extend distally to nearly the plantar surface and proximally superior to the retrocalcaneal bursa (TECH FIG 1).
- Carefully perform sharp dissection to create full-thickness flaps, taking care to identify and protect any branches of the sural nerve.

**TECH FIG 1** • Location of incision.

- Make a longitudinal periosteal incision and extend it proximally through the retrocalcaneal bursa, and excise the retrocalcaneal bursa.
- Elevate the periosteum anteriorly, then elevate it posteriorly.
- Continue sharp elevation of the calcaneal periosteum and Achilles tendon insertion expansion medially along the posterior calcaneal tuberosity all the way to the medial aspect of the tuberosity.
- Subperiosteal exposure of the insertional ossification requires careful dissection to preserve the Achilles sleeve.
- Resect any degenerative tendinosis of the Achilles tendon. If preoperative MRI showed tendinosis affecting greater than 50% of the cross-sectional area of the Achilles tendon, a flexor hallucis longus tendon transfer, described elsewhere, will be necessary.
- Resect the posterior calcaneus along a line from inferior to the insertional ossification to anterior to the posterosuperior process of the calcaneus using a saw or osteotome (TECH FIG 2).
- Round over the sharp edges medially and laterally with a rasp or rongeur.
- Place two suture anchors in the cancellous bone left after ostectomy and repair the Achilles tendon to the calcaneus (TECH FIG 3).
- Repair the periosteum laterally.
- Close the incision.
- Apply a sterile dressing and plaster posterior mold splint with the ankle in resting plantarflexion.

**TECH FIG 2** • Location of ostectomy to include the posterosuperior process of the calcaneus and the insertional calcification.

**TECH FIG 3** • Location of suture anchors and repair of Achilles tendon to ostectomy surface of calcaneus.
PEARLS AND PITFALLS

**Exposure**
- Do not be afraid to lengthen the incision to avoid tension from retraction.
- The incision is posterior to the sural nerve, but there may be a branch to the calcaneus in the field, which should be protected.
- Creating full-thickness tissue flaps and avoiding blunt dissection minimize the risk of wound dehiscence.

**Decompression**
- Elevating the periosteum anterior to the ostectomy will facilitate later repair of the Achilles to the calcaneus.
- Be sure to perform ostectomy anterior to the posterosuperior process of the calcaneus, but be careful to avoid the posterior facet of the subtalar joint.
- A secure repair of the Achilles to the calcaneus permits early motion with minimal risk of early avulsion.

POSTOPERATIVE CARE
- Non-weight-bearing is continued for 4 weeks postoperatively.
- Two weeks after surgery, the postoperative splint is changed to a removable walker boot with an Achilles wedge like that used for nonoperative care.
- The removable walker boot is continued for 6 weeks, for a total of 8 weeks of immobilization.
- Active, nonresistive ankle and hindfoot range-of-motion exercises are begun once the incision has healed.
- Physical therapy begins 8 weeks after surgery.

OUTCOMES
- Fifty to 85% of patients report good or excellent results 2 years after surgery.4,7
- The percentage of good or excellent results is higher in athletic than nonathletic patients.4
- Radiographically recurrent insertional calcification occurs in 50% of patients, but symptoms do not always recur with radiographic recurrence.7
- Some patients have recurrent symptoms without radiographic recurrence.7
- Maximum symptomatic relief may not occur until 12 to 18 months after surgery.
- A 1- to 2-month period of temporary symptomatic recurrence often occurs 7 to 10 months after the surgery.7

COMPLICATIONS
- Superficial or deep infection is especially common in diabetic and overweight patients.
- Delayed wound healing is also especially common in diabetic and overweight patients.
- Paresthesias and hypoesthesias can be avoided by identifying and protecting the sural nerve and its calcaneal branch.
- Achilles avulsion
- Deep venous thrombosis
- Recurrence

REFERENCES
DEFINITION

- The term *insertional Achilles tendinitis* (IAT) is actually a misnomer. The condition is more typically a degenerative process, and the nomenclature should reflect this condition, more appropriately, as a tendinosis or tendinopathy.\(^5,7,8,9,14\)
- As the name suggests, insertional Achilles tendinopathy is identified by a painful condition at the musculotendinous insertion of the tendon Achilles on the posterior calcaneus.
  - It represents about 10% to 20% of all Achilles pathology.\(^2\)
  - It is most commonly seen as an overuse injury in athletes, eg., runners and “push-off” athletes such as basketball or volleyball players, or in more sedentary patients as a degenerative process.

ANATOMY

- The Achilles tendon (TA) is the largest tendon in the body. Its chief function is plantarflexion of the foot and ankle.
- It is viscoelastic and strong, elongating up to 15% under loads and bearing up to 10 times body weight in single-legged stance during running.\(^5,9\)
- The Achilles insertion is a broad expanse that envelopes the entire tuberosity of the os calcis and sends Sharpey’s fibers to the medial, lateral, and plantar borders of the bone.\(^1\)
- Immediately anterior to the Achilles tendon lie the retrocalcaneal bursa and a variably sized posterolateral prominence of calcaneus, often known as Haglund’s deformity.
- More anteriorly lies the deep posterior compartment musculature, which includes the flexor hallucis longus (FHL), the neurovascular bundle, including the tibial nerve, and vessels.
- The FHL originates from the fibula and interosseous membrane, travelling obliquely and distally to pass under the sustentaculum tali, through a fibro-osseous tunnel, and on to the master knot of Henry to attach to the hallux.

PATHOGENESIS

- Repetitive stress can lead to a combination of inflammatory and degenerative changes.
- Degeneration or tendinosis occurs as the already compromised vascularity of the tendon is further reduced by age and injury.\(^5,9\)
  - Microscopic and macroscopic changes occur, leading to scarring and slow regeneration or repair.
  - Tenocytes are reduced in number and quality, contributing to poor repair potential.
- Inflammatory changes are manifested as paratenonitis involving the investing layer surrounding the TA, but not the tendon itself. This leads to thickening and adherence of the paratenon to the TA.
- Additionally, the continuum of injury and inadequate repair capacity create a cycle of collagen and calcium deposition in an effort to stabilize the musculotendinous enthesis, leading to enlargement of the insertion site; generation of abundant, poor quality tissue; and irritation of the surrounding tissues, causing a painful thickening of the insertion of the TA.

NATURAL HISTORY

- Untreated IAT has not been studied extensively. However, surgical findings and histologic analyses have provided some information.
- Persistent IAT leads to continued pain and swelling of the retrocalcaneal heel.
- A vicious cycle occurs in which further injury induces more attempts at repair and scar formation, leading to more irritation of surrounding tissues, decreased vascularity, and further microscopic injury.
- The posterior heel is more difficult to accommodate in a shoe.
- Range of motion is reduced, leading to increased susceptibility to injury with any activity that places the TA under strain.
- Calcific debris is generated, both as reactive tissue response to injury and intratendinous hematoma formation as a result of injury. This compromises the viscoelasticity and, therefore, the integrity of the tendon, making it more apt to tear, either partially or completely.\(^4,14\)
- A less pliable, less resilient TA is the end product. Insertional avulsion or rupture may occur, presenting a difficult treatment dilemma.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients provide fairly accurate descriptions and complain of pain at the bone–tendon interface on the retrocalcaneal heel.
- Pain may be worse after activity, but gradually becomes more pervasive.
- Athletes may note an increase in symptoms with increases in training intensity or duration or changes in surface or shoes.
- Examination demonstrates tenderness directly posteriorly on the heel or, often, posterolaterally.
- In advanced cases, thickening, nodularity, or hardening may be palpated.
- Dorsiflexion of the ankle may be reduced compared with the contralateral leg.
- Methods for examining the Achilles tendon and its insertion include:
  - Direct palpation
  - The posterior heel and TA are inspected for visual or palpable swelling, tenderness, nodularity, or gapping, all of which are suggestive of diseased tendon.
  - Thompson test
  - With the patient prone, squeeze the calf at the gastrocnemius–soleus junction to elicit plantarflexion of the foot.
Compare with the contralateral side. A positive test is identified when the excursion of the injured side is far less than its uninjured counterpart. This is evidence for complete rupture.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

**Radiographs**
- Radiographs often are not necessary for diagnosis, but they are helpful in determining the presence of calcific debris, which is a poor prognostic sign. (FIG 1).
- Plain lateral and axial radiographic views usually are sufficient.

**Ultrasonography**
- Ultrasonography is a relatively inexpensive and accurate way to determine tendon quality, integrity, and function.
  - It has the advantage of being used dynamically to watch active tendon excursion, if so desired. It also may be used to follow the course of healing.
  - It is a highly user-dependent tool.

**MRI**
- MRI probably is the most comprehensive study available for investigation and evaluation of a damaged Achilles tendon (FIG 2 A,B).
  - This study gives the most accurate information regarding degree of TA involvement, quality of surrounding tissue, presence or absence of rupture, and other concomitant pathology.

**DIFFERENTIAL DIAGNOSIS**
- Retrocalcaneal bursitis
- Haglund syndrome
- Inflammatory arthritides
- Seronegative spondyloarthropathies
- Gout
- Familial hyperlipidemia
- Sarcoidosis
- Diffuse idiopathic skeletal hyperostosis
- Pharmacologically induced pathology
  - Fluoroquinolone use
  - Chronic corticosteroid use

**NONOPERATIVE MANAGEMENT**
- Nonoperative treatment is successful in over 90% of patients with this process.\(^5^,8\)
  - Success rates decline in the face of greater age at time of presentation, longstanding symptoms, and evidence of calcific tendinosis.\(^8\)
  - Initial phases of treatment include NSAID use, heel lifts, eccentric stretching, and shoe modifications to widen and soften the heel counter.
  - More advanced situations may call for formal orthoses to correct any biomechanical abnormality, night splinting to apply continual stretch to the TA, and therapy modalities such as ice, contrast baths, and iontophoresis.
  - Severe cases may require immobilization in a cast or boot, followed by gradual reintroduction to cross-training before return to regular sports or activities.

**SURGICAL MANAGEMENT**
- Surgical decision making should reflect failed conservative efforts and continued symptoms and functional impairments.
- Younger, more athletic patients often respond to a simple débridement of damaged TA, which usually accounts for less than 50% of the total tendon. A midline tendon-splitting approach to this débridement is our preferred procedure for these patients.

**Preoperative Planning**
- Tendon integrity becomes more questionable with involvement of more than 50%, so augmentation is entertained at
this point. This extensive involvement may become evident on preoperative testing or, alternatively, on intraoperative evaluation.

- Ideally, the surgeon will already have a good idea before beginning the procedure as to whether an augmentation is necessary.
  - This is readily apparent on imaging.
  - One must be ready to add this procedure if it is found to be necessary intraoperatively.

### Positioning

- The patient is placed in the prone position (Fig 3).
- Both feet are prepped into the surgical field, up to the level of the knees.

### Approach

- A midline incision currently is preferred (Fig 4), beginning about 2 to 3 cm proximal to the insertion and extending distally to expose the entire insertion of the TA.

---

**RETROCALCANEAL DÉBRIDEMENT**

- Full-thickness flaps should be developed medially and laterally, including the substance of the Achilles tendon (Tech Fig 1A).
- All nonviable or suspect-appearing tissue should be removed (Tech Fig 1B).

---

**Tech Fig 1**

- A. A midline tendon-splitting incision is made with full-thickness flaps through the TA.
- B. The retrocalcaneal bursa is visualized through the tendon.

- Once adequate débridement takes place, the retrocalcaneal bursa also can be excised.
- Any enlarged or impinging posterolateral prominence of calcaneus should be aggressively removed with a ronguer, oscillating saw, or osteotome.
FLEXOR HALLUCIS LONGUS HARVEST

- The FHL muscle belly usually is easily visible after the débridement is complete (TECH FIG 2A).
- Trace the FHL into its fibro-osseous tunnel (TECH FIG 2B,C).
- Plantarflex the ankle and hallux maximally.
- With a no. 15 blade, transect the tendon as distally as possible while an assistant pulls posteriorly on the proximal portion of the tendon (TECH FIG 2D).
- An interlocking suture of 2-0 braided nonabsorbable material is sewn into the tendon stump.

ATTACHING THE GRAFT

- A 6.5-mm vertical tunnel is created in the posterior calcaneus about 1 cm anterior to the previous Achilles insertion (TECH FIG 3A).
- The FHL suture is passed through the tunnel and through the plantar skin with a Beath pin, bringing the FHL tendon into the tunnel (TECH FIG 3B).
- Tensioning is ensured by using the other foot as a reference at about 15 to 20 degrees of resting equinus. If the most medial and lateral remnants of native Achilles are maintained, they will also serve as reference for proper tensioning.
- An absorbable interference screw is introduced for graft fixation (TECH FIG 3C).
- Tension and range of motion are assessed and should be roughly equal to that of the uninjured limb (TECH FIG 3D).
- The FHL muscle belly is then sewn in a side-to-side tenodesis fashion to the remaining TA to promote vascularity and help restore power to push-off (TECH FIG 3E).
WOUND CLOSURE

- Layered closure is performed with a 2-0 absorbable monofilament in the paratenon, if any is left.
- 2-0 monocryl suture is used for subcutaneous fat.
- Skin is closed with 3-0 nylon suture.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Decision to augment</th>
<th>All studies must be evaluated thoroughly and the tendon inspected carefully at the time of surgery to ensure TA insertional integrity. Any question regarding stability of insertion should prompt consideration for augmentation.</th>
</tr>
</thead>

</tbody>
</table>
POSTOPERATIVE CARE

- Immediately postoperatively, the foot is splinted in 15 to 20 degrees of equinus for 2 weeks.
- The patient is then placed in a walking boot with a 2-inch heel lift for another 2 weeks and allowed to gently touch down to the floor. (Noncompliant patients receive a walking cast.)
- At 1 month, patients are instructed on gentle active-assisted range of motion and permitted to progress to full weight bearing as tolerated.
- Over the next 2 months, the heel lift is gradually reduced in height until a painless plantigrade foot is achieved.
- Physical therapy is begun at 6 to 8 weeks after surgery.

OUTCOMES

- Treatment of IAT by simple débridement is useful in younger patients, but more unpredictable as the extent of disease or patient age increases.5
- Several studies have shown substantial healing times after débridement alone, and even further compromise and poor predictability with evidence of intratendinous calcific debris.14
- The success of the procedure depends on how thoroughly débridement of involved tissue is performed; however, beyond 50% tendon compromise, the stability of the insertion comes into question.
- Augmentation with the FHL tendon has been shown to be technically reproducible and statistically successful.6,12,13,15
  - In one series, 20 patients undergoing this procedure for chronic Achilles tendon insufficiency revealed no postoperative reruptures, tendinopathy recurrences, or wound complications.13
  - Despite presumed and reported differences in calf circumference and push-off strength, these differences seem well tolerated and acceptable to patients when compared to the substantial amount of pain relief and restoration of function they receive.15
- The technique, as described, modifies classic descriptions in several ways:
  - Deviation from the classic two-incision technique,6,12,13 thus reducing morbidity of another surgical site
  - Maintaining more native FHL bulk and function by preserving distal vincular tendon11 attachments at the master knot of Henry. Theoretically, this will reduce the push-off strength morbidity associated with this procedure.
  - Decision regarding augmentation can be made after Achilles débridement determines insertional integrity, because the FHL harvest may be performed through the same incision as the débridement of the TA.
- Less tendon is needed because tendon transfer fixation is equal to or better than the side-to-side single-looped method because of interference screw fixation of the tendon directly to bone.3,10

COMPLICATIONS

- Wound complications
- Inadequate tendon débridement
- Inadequate bone resection
- Tibial nerve injury
- Fracture through bone tunnel
- Over- or under-tensioning the tendon transfer

REFERENCES

DEFINITION

- Tendinopathy of the Achilles tendon involves clinical conditions in and around the tendon arising from overuse.\(^1\)
- Tendinopathy of the Achilles tendon is common both in athletic and nonathletic individuals. It can affect several regions of the tendon.
- One particularly common site is the main body of the tendon, 2 to 4 cm from its insertion on the calcaneus.\(^2\)

ANATOMY

- The two heads of gastrocnemius (medial and lateral) arise from the condyles of the femur. As the muscle fibers descend, they insert into a broad aponeurosis that contracts and receives the tendon of the soleus on its deep surface to form the Achilles tendon.\(^3\)
- The Achilles tendon is the thickest and strongest tendon in the body. About 15 cm long, it originates in the midcalf and extends distally to insert into the posterior surface of the calcaneus. Throughout its length, it receives muscle fibers from the soleus on its anterior surface.\(^4\)

PATHOGENESIS

- To date, the etiopathogenesis of Achilles tendinopathy remains unclear.
- Tendinopathy has been attributed to a variety of intrinsic and extrinsic factors.\(^6\)
- It has been linked to overuse vascularity, dysfunction of the gastrocnemius-soleus, age, gender, body weight and height, endocrine or metabolic factors, deformity of the pes cavus, lateral instability of the ankle, the use of quinolone antibiotics, excessive movement of the hindfoot in the frontal plane, marked forefoot varus, changes in training pattern, poor technique, previous injuries, footwear, and environmental factors such as training on hard, slippery, or slanting surfaces.\(^1\)–\(^6\)
- Most of the above factors should be considered associative, not causative, evidence, and their role in the cause of the condition is therefore still debatable.\(^7\)

NATURAL HISTORY

- Although Achilles tendinopathy has been extensively studied, there is a clear lack of properly conducted scientific research to clarify its cause, pathology, natural history, and optimal management.\(^8\)
- The management of Achilles tendinopathy lacks evidence-based support, and tendinopathy sufferers are at risk of long-term morbidity with unpredictable clinical outcome.\(^9\)
- Most patients respond to conservative measures, and the symptoms can be controlled, especially if the patients accept that a decreased level of activities may be necessary.\(^9\)
- In 24% to 45.5% of patients with Achilles tendinopathy, conservative management is unsuccessful, and surgery is recommended after exhausting conservative methods of management, often tried for 3 to 6 months. However, longstanding Achilles tendinopathy is associated with poor postoperative results, with a greater rate of reoperation before reaching an acceptable outcome.\(^10\),\(^11\)
- As the biology of tendinopathy is being clarified, more effective management regimens may come to light, improving the success rate of both conservative and operative management.\(^12\)

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present with pain located 2 to 6 cm proximal to the insertion of the tendon and felt after exercise.
- As the pathologic process progresses, pain may occur during exercise, and, when severe, may interfere with activities of daily living.
- Runners experience pain at the beginning and at the end of a training session, with a period of diminished discomfort in between.
- The foot and the heel should be inspected for malalignment, deformity, obvious asymmetry in the size of the tendon, localized thickening, a Haglund heel, and any previous scars.\(^11\)–\(^13\)
- The tendon should be palpated to detect tenderness, heat, thickening, nodularity, and crepitation.
- The “painful arc” sign helps to distinguish between lesions of the tendon and paratenon. In paratendinopathy, the area of maximum thickening and tenderness remains fixed in relation to the malleoli from full dorsiflexion to plantarflexion, whereas lesions within the tendon move with movement of the ankle.\(^14\)

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain soft tissue radiography is useful in diagnosing associated or incidental bony abnormalities.\(^9\)
- Ultrasound is the primary imaging method, since it correlates well with the histopathologic findings despite being operator-dependent.\(^12\)
- Ultrasound promptly identifies hypoechoic areas, which have been shown at surgery to consist of degenerated tissue, and increased thickness of the tendon.
- MRI studies should be performed only if the ultrasound scan remains unclear.
- MRI provides extensive information on the internal morphology of the tendon and the surrounding structures and is useful in evaluating the various stages of chronic degeneration and in differentiating between peritendinitis and tendinosis. Areas of mucoid degeneration are shown on MRI as a zone of high signal intensity on T1- and T2-weighted images.\(^13\)

DIFFERENTIAL DIAGNOSIS

- Paratendinopathy of the Achilles tendon, acute or chronic rupture of the Achilles tendon, rerupture of the Achilles tendon.
tendon, tear of the musculotendinous junction of the gastrocnemius-soleus and the Achilles tendon.

NONOPERATIVE MANAGEMENT

- There is weak evidence of a modest benefit of nonsteroidal anti-inflammatory drugs (NSAIDs) for the alleviation of acute symptoms.
- Low-dose heparin, heel pads, topical laser therapy, and peritendinous steroid injection produced no difference in outcome when compared with no treatment.
- Medications shown to be effective in randomized controlled trials include peritendinous injection of aprotinin, topical application of glyceryl trinitrate, and the use of ultrasound-guided sclerosing injections in the area of neovascularization.
- Painful eccentric calf-muscle training can be an effective treatment for noninsertional Achilles tendinopathy.
- Eccentric loading and low-energy shock-wave therapy show comparable results.

SURGICAL MANAGEMENT

- Conservative management is unsuccessful in 24% to 45.5% of patients with tendinopathy of tendo Achilles.
- Surgery is recommended after at least 6 months of conservative management.
- The objective is to excise fibrotic adhesions, remove degenerated nodules, and make multiple longitudinal incisions in the tendon to detect intratendinous lesions and to restore vascularity, possibly stimulating the remaining viable cells to initiate a response in the cell matrix and healing.
- The defect can be sutured in a side-to-side fashion or left open.
- Reconstruction procedures may be required if large lesions are excised.

Preoperative Planning

- Preoperative imaging studies can guide the surgeon in the placement of the incision and in incising the tendon sharply in line with the tendon fiber bundles.

Positioning

- Under locoregional anesthesia, the patient is placed prone with the ankles clear of the operating table.
- The prone position allows excellent access to the affected area.
- Alternatively, the patient can be positioned supine with a sandbag under the opposite hip and the affected leg positioned in a figure 4 position.
- A tourniquet is applied to the limb to be operated on. The limb is exsanguinated, and the tourniquet is inflated to 250 mm Hg.

Approach

- The incision is made on the medial side of the tendon to avoid injury to the sural nerve and short saphenous vein (TECH FIG 1).
- A straight posterior incision may also be more bothersome with the edge of the heel counter pressing directly on the incision.
- Maintaining thick skin flaps is vital to reduce the incidence of wound breakdown.

Expose the paratenon and the Achilles tendon (TECH FIG 1).
Identify and incise the paratenon (TECH FIG 2).
In patients with evidence of coexisting paratendinopathy, the scarred and thickened tissue is generally excised.
Based on preoperative imaging studies, the tendon is incised sharply in line with the tendon fiber bundles (TECH FIG 3).

The tendinopathic tissue can be identified as it generally has lost its shiny appearance and it frequently contains disorganized fiber bundles that have more of a “crab-meat” appearance (TECH FIG 4).
Sharply excise this tissue (TECH FIG 5).
The remaining gap can be repaired using a side-to-side repair, but we leave it unsutured (TECH FIG 6).
Suture the subcutaneous tissues with absorbable material (TECH FIG 7).

The skin edges are juxtaposed with Steri-Strips (TECH FIG 8) and then a routine compressive bandage. The limb is immobilized in a below-knee synthetic weight-bearing cast with the foot plantigrade.

If significant loss of tendon tissue occurs during the débridement, consider a tendon augmentation or transfer.

A tendon turndown flap has been described for this purpose. With a turndown procedure, one or two strips of tendon tissue from the gastrocnemius tendon are dissected out proximally while leaving the strip attached to the main tendon distally. It is then flipped 180 degrees and sewn in to cover and bridge the weakened defect in the distal tendon.

A plantaris weave has also been reported for this purpose. The plantaris tendon can be found on the medial edge of the Achilles tendon. It can be traced proximally as far as possible and detached as close as possible to the muscle tendon junction to gain as much length as possible.

It can be left attached distally to the calcaneus, looped and woven through the proximal Achilles tendon, and sewn back onto the distal part to the tendon.

Alternatively, the plantaris can be detached distally as well and used as a free graft.

The tourniquet is deflated and the time recorded. 

---

**TECH FIG 3** - Longitudinal tenotomy along the tendon fibers. Note that as the tendon fibers rotate 90 degrees, the longitudinal tenotomy has to follow them.

**TECH FIG 4** - The macroscopic appearance of the tendinopathic area is visualized.

**TECH FIG 5** - The tendinopathic tissue is excised.

**TECH FIG 6** - Appearance at the end of the procedure.

**TECH FIG 7** - The skin wound after suture of the deep tissues.

**TECH FIG 8** - Steri-Strips are applied to the surgical wound before a routine compressive bandage. The limb is then immobilized in a below-knee synthetic weight-bearing cast with the foot plantigrade.
FOOT AND ANKLE • Section V  SPORTS-RELATED PROCEDURES FOR ANKLE AND HINDFOOT

PEAKS AND PITFALLS

**Diagnosis**
- Diagnosis is usually made on a clinical basis, including a careful history and physical examination.
- Ultrasound can identify hypoechoic areas, which have been shown at surgery to consist of degenerated tissue, and increased thickness of the tendon.
- MRI studies should be performed only if the ultrasound scan remains unclear.

**Positioning**
- Prone position, with thigh tourniquet.

**Incision**
- An incision placed medial and anterior to the medial border of the Achilles tendon reduces the likelihood of injury to the sural nerve and short saphenous vein.

**POSTOPERATIVE CARE**

- A period of initial splinting and crutch walking is generally used to allow pain and swelling to subside. In addition, wound healing complications are difficult to manage and an initial period of immobilization may promote skin healing.
- After 14 days, the wound is inspected and motion exercises are initiated. The patient is encouraged to start daily active and passive ankle range-of-motion exercises. The use of a removable walker boot can be helpful during this phase. Weight bearing is not limited according to the degree of débridement needed at surgery, and early weight bearing is encouraged. However, extensive débridements and tendon transfers may require protected weight bearing for 4 to 6 weeks postoperatively.
- After 6 to 8 weeks of mostly range-of-motion and light resistive exercises, initial tendon healing will have been completed. More intensive strengthening exercises are started, gradually progressing to plyometrics and eventually running and jumping.13,14

**OUTCOMES**

- The surgical procedure is commonly successful, but patients should be informed of the potential failure of the procedure, risk of wound complications, and at times prolonged recovery time.6
- Rehabilitation is focused on early motion and avoidance of overloading the tendon in the initial healing phase.

**COMPLICATIONS**

- Wound healing problems
- Infection
- Sural nerve injury
- Rupture of Achilles tendon
- Deep vein thrombosis

**REFERENCES**

DEFINITION
- Insertional and midsubstance Achilles tendinosis is a painful degenerative process that arises due to mechanical and vascular factors and affects the paratenon and collagen fibers.
- It is most commonly seen in patients in their mid-40s and older.

ANATOMY
- The Achilles tendon, the largest tendon in the body, connects the gastroc–soleus complex to the calcaneus (FIG 1).
- It is covered by a paratenon without a definite tendon sheath.
- The blood supply of the tendon arises distally from calcaneal arterioles and proximally from intramuscular branches. There is a relatively hypovascular, or watershed, area 2 to 4 cm proximal to the tendon insertion.

PATHOGENESIS
- Mechanical and vascular factors contribute to the development of tendinosis. The process begins with mechanical pressure on the insertion of the Achilles tendon from internal factors, a Haglund’s deformity, or external factors, such as a firm heel counter. Retrocalcaneal bursitis develops initially without Achilles tendon involvement. Increasing prominence of the posterolateral calcaneal tuberosity or hindfoot malalignment (ie, varus heel), can cause tendon collagen fiber injury and further inflammation of the retrocalcaneal bursa.
- Progressive thickening of the retrocalcaneal bursa and peritendinous tissue increases mechanical pressure on the tendon, impeding blood flow and hampering the normal repair process, leading to a thickened, degenerative tendon.

With dysvascular changes associated with aging, the tendon becomes increasingly thick and painful. Radiographs at this point may show a spur or calcification at the Achilles insertion.

NATURAL HISTORY
- The natural history of the pathologic process most likely is a continuum that begins with retrocalcaneal bursitis and ends in chronic Achilles tendinosis.
- Patient activity becomes more restricted due to increased pain and weakness.
- Age-dependent changes in collagen quality and decreased vascularity contribute to the development of tendinosis.
- As the degenerative process becomes chronic, the tendon becomes mechanically deficient and more susceptible to rupture.
- Symptoms become unremitting as the disease progresses.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Achilles tendinosis causes pain and swelling of the diseased segment of tendon.
- Pain increases with physical activity and with direct pressure on the affected tendon.
- Patients with seronegative arthropathies, spondyloarthropathies, hypercholesterolemia, sarcoidosis, and renal transplant have an increased incidence of Achilles tendinopathy.
- The patient should be assessed for hyperpronation or heel varus deformities, which can cause eccentric Achilles tendon loading. If either is present, an orthosis to keep the hindfoot in neutral may be necessary.
- Ankle dorsiflexion is measured with the knee flexed and extended to assess for gastrocnemius or Achilles tendon tightness. If excessive tightness is present, a gastrocnemius recession should be considered along with the flexor hallucis longus (FHL) transfer.
- With the patient prone on the examining table, the Achilles tendon is palpated to localize the area of thickening and tenderness (either insertional or noninsertional). Assess the size of the calcaneal tuberosity; if it is enlarged, excision of this prominence should be considered to reduce mechanical pressure on the diseased Achilles tendon.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs are useful in evaluating the extent of tendon calcification and presence of a Haglund’s deformity (FIG 2).
- Although MRI scanning is not essential for preoperative planning, it can be beneficial in estimating the amount of degenerative tendon to be excised (FIG 3).

DIFFERENTIAL DIAGNOSIS
- Haglund’s deformity
- Os trigonum

FIG 1 • The Achilles tendon and its relationship to the flexor hallucis longus tendon.
Part 8 FOOT AND ANKLE • Section V SPORTS-RELATED PROCEDURES FOR ANKLE AND HINDFOOT

Retrocalcaneal bursitis
Peritendinitis
Seronegative spondyloarthropathy
Insertional tendinopathy
Achilles tendinosis

NONOPERATIVE MANAGEMENT

- Nonsurgical treatment of insertional or noninsertional Achilles tendinosis includes rest, immobilization, and rehabilitation.
- Immobilization can include casting, a cast brace, and a custom molded ankle foot orthosis (AFO).
- Structural abnormalities such as heel varus are addressed with wedges or orthotics, or both.
- Training regimens are modified to reduce stress on the affected tendon.
- Physical therapy for heavy-load eccentric strengthening exercises has been found to be effective for Achilles tendinopathy and may be superior to conventional treatment regimens and comparable to open débridement of the tendon.

SURGICAL MANAGEMENT

- Surgery is performed only on those patients who have intractable pain and impaired function or those who have failed previous tendon débridement or Haglund’s resection alone. Most people in this patient group have a chronic Achilles tendon deficiency, and are sedentary, overweight, and have radiographic or MRI evidence of a thickened, calcific Achilles insertion.
- Most treatments that have been described focus on removing mechanical pressure from the diseased tendon (eg, excising the posterosuperior calcaneal tuberosity), débridement of the diseased tendon, or augmentation of the remaining, débrided tendon (ie, FHL, peroneus brevis, plantaris).
- The bulk of surgical treatment is discussed in the following sections and in the Techniques section.

Preoperative Planning

- The extent and location of diseased tendon must be identified. The area of tendon degeneration most often is the distal 2 to 4 cm. The degeneration also may be isolated at the mid-substance.
- The patient must understand preoperatively that the time to maximum improvement could be prolonged (average 8.2 months).
- If the surgeon wants to loop the transferred FHL through the calcaneus at the time of the transfer and more tendon length consequently will be needed, the FHL should be harvested from the midmost at Henry’s knot and pulled out the posterior incision.

Positioning

- The patient is placed prone on the operating table with a soft bump anterior to the ankle (FIG 4).

Approach

- Various incisions have been used to approach the diseased tendon.
  - Incisions that have been recommended include central splitting, medial and/or lateral longitudinal pretentious, or medial with a transverse L-shaped extension distally.
  - All of these incisions can be used successfully to expose and débride diseased tissue, but if augmentation of the Achilles tendon is anticipated, a medial incision will give the best access to the FHL.
  - Whatever incision is selected, it should be done sharply through the subcutaneous tissue to the paratenon, taking care not to dissect horizontally, thus reducing the risk of vascular compromise of the soft tissues overlying the tendon.

FIG 2 • Lateral radiograph of the heel revealing a prominent calcaneal tuberosity and calcification of the Achilles insertion.

FIG 3 • A. This sagittal MRI scan demonstrates increased signal in the Achilles insertion. B. This axial MRI scan of the Achilles insertion reveals diseased fibers.

FIG 4 • The patient is positioned prone on the operating table.
FLEXOR HALLUCIS LONGUS TRANSFER OR AUGMENTATION FOR ACHILLES TENDINOSIS

A 10-cm posteromedial incision is made starting near the junction of the proximal and middle thirds of the Achilles tendon and stopping distally at the tendinous insertion into the calcaneal tuberosity. The incision is made sharply through the subcutaneous tissue to the paratenon, taking care not to dissect horizontally, thereby reducing the risk of vascular compromise of the soft tissue overlying the Achilles tendon. An L-shaped extension of the incision distally is performed if extensive débridement of the Achilles tendon is anticipated and better exposure of the lateral tendon insertion is needed (TECH FIG 1).

The substance of the tendon is carefully inspected. Any amorphous (codfish-flesh appearing), calcified, or ossified tissue of the tendon is excised, leaving only relatively healthy, normally striated tissue. Usually, more than 50% of the cross-section is removed. The degenerative, calcified area of tendon is best excised by removing a wedge-shaped piece of tissue from the insertion of the Achilles tendon (TECH FIG 2).

In all cases, a partial calcaneal ostectomy is performed at the superoposterior aspect to decompress the Achilles tendon insertion (TECH FIG 3). This also improves exposure to the anterior aspect of the tendon, aiding in tendon inspection and débridement.

With the degenerative tissue removed, the triangular fat pad anterior to the Achilles tendon is excised, exposing the deep posterior fascia (TECH FIG 4). The fascia overlying the posterior compartment of the leg is incised longitudinally to the proximal extent of the FHL muscle body. The FHL tendon is identified (TECH FIG 5). The flexor retinaculum is released along the medial aspect of the hindfoot to further expose the FHL.

Gentle retraction of the neurovascular bundle with a blunt retractor allows safe visualization of the tendon distally (TECH FIG 6). The FHL is transected as far distal as possible with the ankle and hallux in maximum plantarflexion. Transection of the tendon is done medial to lateral to avoid accidental injury to the neurovascular structures.

The tendon is brought posteriorly and positioned at the calcaneus between the two limbs of the remaining débrided Achilles insertion (TECH FIG 7). If more length of the FHL is needed, the origin of the more distal muscle fibers of the FHL can be detached bluntly from the fibula and interosseous ligament to increase the excursion of the FHL. Proper tensioning of the FHL transfer is determined by dorsiflexing the ankle to place the Achilles tendon at maximal stretch. With the FHL appropriately tensioned, any excess length of the tendon is removed to allow optimal pull of the transferred tendon to the calcaneus.

TECH FIG 5 • The flexor hallucis longus (FHL) tendon is exposed after the deep fascia is split.
**Chapter 119**

**FLEXOR HALLUCIS LONGUS TRANSFER FOR ACHILLES TENDINOSIS**

**TECH FIG 6**
- A. The flexor retinaculum is split to expose the FHL distally.
- B. The neurovascular bundle is protected with a deep retractor.

**TECH FIG 7**
- A. The FHL is pulled posteriorly and checked for length.
- B. Drawing of FHL placement between the limbs of the remaining Achilles tendon.
- C. The FHL is tightly positioned against the Achilles tendon.
The transferred tendon is held with a two-strand suture anchor (TECH FIG 8). The first strand of suture is used in modified Kessler fashion to secure the FHL to the calcaneus at the proper tension (TECH FIG 9). The second strand is used as a whipstitch to add pullout strength (TECH FIG 10). The FHL tendon is sutured to the Achilles tendon in side-to-side fashion with nonabsorbable braided suture (TECH FIG 11).

- A careful, layered closure of the paratenon, subcutaneous tissue, and skin is performed.
## PEARLS AND PITFALLS

| FHL harvest | ■ Protect the neurovascular bundle with a deep retractor through the medial incision while exposing the FHL for transfer to avoid injuring adjacent vital structures.  
■ Cut the tendon with a no.15 blade medial to lateral to avoid injury to the neurovascular bundle.  
■ Maximally plantarflex the ankle and great toe, and pull on the FHL before cutting the tendon to obtain adequate length of the transferred tendon. |
| FHL transfer | ■ Dorsiflex the foot while placing the FHL transfer at maximal stretch to determine the proper insertion point and tensioning of the transferred tendon.  
■ Make sure there is good apposition between the FHL and remaining Achilles tendon by excising all interposed fat and using nonabsorbable sutures to hold the repair. |
| Skin closure | ■ Perform careful, separate layer closure, starting with the paratenon, to avoid excessive scarring. |

## POSTOPERATIVE CARE

- A compressive dressing with splints is applied in the operating room with the ankle in neutral position. The initial dressing is kept in place for 10 to 14 days. At that time, if the incision is well healed and the reconstruction was deemed stable at the time of operation, the patient is placed in a controlled ankle motion (CAM)-soled walker, and weight bearing as tolerated is allowed.

- If more than 75% of the Achilles tendon has been débrided, a weight-bearing cast is applied for 4 weeks to provide extra support for the healing tendon.

- Range-of-motion and strengthening exercises are begun 6 to 8 weeks postoperatively if clinical improvement (decreased pain and swelling) is evident.

- The patient is weaned from the CAM-soled walker at 10 to 12 weeks as symptoms of pain and swelling allow.

## OUTCOMES

- Hansen reported a proximal FHL transfer technique with good or excellent results. Emphasis was placed on thoroughly excising the diseased tendon.

- Wapner reported good to excellent pain relief and improved function in seven patients with Achilles débridement and FHL transfer harvested from the midfoot for tendinosis.

- Wilcox et al., using the American Orthopaedic Foot and Ankle Society (AOFAS) hindfoot score and the SF-36 Health Survey, reported overall good results with FHL transfer in 20 patients with recalcitrant Achilles tendinosis but found that patient function may not improve.

- Den Hartog reported significant improvement in the postoperative AOFAS hindfoot scores in 29 patients who underwent FHL transfer for severe Achilles tendinosis.

## COMPLICATIONS

- Rerupture of the augmented Achilles

- Wound necrosis secondary to undermining of soft tissues

- Infection

- Scarring secondary to inadequate repair of the paratenon

- Persistent pain and swelling

## REFERENCES

DEFINITION

- The plantaris tendon is an ideal source for soft tissue augmentation for ligament reconstructions or tendon repair.\(^1\),\(^14\)
- The plantaris tendon has high tensile strength with the structured collagen characteristic of physiologic tendons.
- Harvest of the plantaris tendon rarely creates appreciable donor site morbidity.
- The goal of this chapter is to provide the foot and ankle surgeon with a simple and reliable method to harvest readily available local tissue for plantaris tendon grafting even if its harvest was not originally planned.

ANATOMY

- The plantaris muscle originates from the lateral femoral condyle, courses along the lower leg’s superficial posterior compartment, and has its musculotendinous junction just distal to the level of the knee joint.
- The proximal plantaris tendon is situated between the gastrocnemius and the soleus muscle. Distally, it lies immediately adjacent to the Achilles tendon in the distal third of the lower leg and typically inserts in the calcaneal tuberosity (FIG 1A).
- The length of the plantaris tendon ranges from 30 to 45 cm.\(^11\)
- The plantaris tendon insertion is variable.\(^3\),\(^4\),\(^11\)
  - In addition to inserting on the calcaneal tuberosity, it may insert at the bursa calcanei, retinaculum flexorum, ankle capsule, plantar aponeurosis, or blend with the Achilles tendon or intermuscular septum (FIG 1B).
  - Because of this variability, distal harvesting procedures are unsuccessful in about 12% to 20% of cases.\(^4\),\(^9\),\(^12\)
  - In about 6% to 7% of individuals, the plantaris tendon is absent. In humans, the plantaris muscle and tendon serve little function; however, early in evolution, it was far more developed in monkeys.\(^3\),\(^8\),\(^10\),\(^11\) Therefore, harvesting the plantaris tendon in humans causes no appreciable donor site morbidity.\(^2\),\(^7\)–\(^9\)
- Bohnsack et al\(^1\) compared highest tensile strength per cubic millimeter (N/mm\(^3\)) of commonly used autografts:
  - Peroneus longus, 61 N/mm\(^3\)
  - Peroneus brevis, 41 N/mm\(^3\)
  - Plantaris, 94 N/mm\(^3\)
  - Achilles split, 36 N/mm\(^3\)
  - Fascia lata, 27 N/mm\(^3\)
  - Periosteal flap, 2 N/mm\(^3\)
  - Corium, 12 N/mm\(^3\)
  - Anterior talofibular ligament, 8 N/mm\(^3\)
- They found the plantaris tendon to have the highest N/mm\(^3\).

PATHOGENESIS

- Chronic joint instability and chronic tendon ruptures develop over months to years.
- In joint instability, acutely torn ligaments eventually scar in an elongated state.

FIG 1 • Anatomy of the plantaris tendon. A. The only tubular structure between the soleus and the gastrocnemius muscles is the plantaris tendon. Therefore, blind dissection between these muscles does not risk nerves and vessels. Major vessels run underneath the soleus muscle. B. Insertions of the plantaris tendon are variable and may complicate the successful harvesting procedure.
Acute untreated tendon ruptures, similarly, eventually demonstrate degeneration and elongation.

Both chronic ligament and tendon injuries eventually may become so degenerated that surgical reconstruction is not possible with residual local tissue, especially in the case of chronically attenuated ligaments or tendons that have been subjected to repeated trauma or microtrauma. These situations lend themselves well to plantaris autografting.

PATIENT HISTORY AND PHYSICAL FINDINGS

Although isolated plantaris tendon ruptures have been reported, no specific physical examination technique has been developed that can isolate the plantaris tendon to confirm in advance that it is present when plantaris tendon harvest is being considered.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Ultrasound is useful in identifying the presence of a plantaris tendon and has a high specificity.10

When MRI is used to evaluate an injury to the ankle ligament or tendon, the imaging study also may prove useful in identifying the presence of an ipsilateral plantaris tendon that may be used for tissue augmentation.7,8,13

SURGICAL MANAGEMENT

The plantaris tendon is ideal tissue for most ligament or tendon augmentations in the foot and ankle, especially because it typically is in the sterile field for virtually every foot and ankle procedure.

Preoperative Planning

If an MRI scan was obtained to determine the initial pathology, it can be used to identify the existence of the plantaris tendon before surgery.8,13

If not, a preoperative ultrasound examination is helpful.10,13

Positioning

Harvest of the plantaris tendon is relatively simple, regardless of which patient position is dictated by the particular foot and ankle procedure.

No tourniquet is needed for plantaris tendon harvesting.

Approach

The proximal approach is a 2-cm longitudinal incision about 30 cm proximal to the medial malleolus (FIG 2).

The distal approach is a 2-cm longitudinal incision at the medial Achilles insertion on the medial calcaneal tuberosity (FIG 3).

The plantaris may be harvested from a proximal or distal approach; for both approaches, only a minimally invasive, 2-cm incision is required.

AUTHORS’ PREFERRED TECHNIQUE FOR PROXIMAL PLANTARIS HARVESTING6,7

Subcutaneous blunt dissection to the fascia is performed with care taken to protect the saphenous nerve and vein (TECH FIG 1A). A 2-cm longitudinal incision is made in the fascia to enable the surgeon’s finger to enter the intermuscular space (TECH FIG 1B). The only tubular structure that runs between the gastrocnemius and the soleus muscle bellies is the plantaris tendon. No nerves or vessels are at risk.13

The tendon is mobilized with the finger or a nerve retractor (TECH FIG 1C).

The plantaris tendon is isolated in a distal direction using a blunt tendon stripper. The tendon stripper is ad-
TECH FIG 1 • A. Blunt spreading of the subcutaneous fat down to the fascia without damage to the saphenous nerve or vein. B. A 2-cm fascial incision is made, and blunt dissection is carried out further down between the gastrocnemius and soleus muscles with the surgeon’s finger. C. The plantaris tendon is developed with a nerve retractor. D. Introduction of the tendon stripper. E. The harvested autograft usually is about 30 cm long.

DISTAL PLANTARIS HARVEST

A 2-cm skin incision is made at the medial border of the Achilles tendon insertion at the calcaneal tuberosity (see Fig 3).

Blunt dissection is carried down to the Achilles tendon and the plantaris tendon. The variability of the plantaris insertions may necessitate a slightly more involved dissection to identify the distal extent of the plantaris tendon (see Fig 1B).

The tendon is mobilized and harvested with a blunt tendon stripper from distal to proximal (TECH FIG 2A).

At the level of the popliteal fossa, the inner cylinder of the stripper is rotated to transect the tendon (TECH FIG 2B). The tendon is stored in a wet sponge until it is needed for ligament or tendon augmentation.

The skin is closed with interrupted sutures and adhesive strips.
Chapter 120  PROXIMAL MINI-INVASIVE GRAFTING OF PLANTARIS TENDON

POSTOPERATIVE CARE

- Adhesive wound strips can reduce skin tension and broadening of the scar.
- After wound healing the patient may use scar massage to reduce subcutaneous adhesions.

OUTCOMES

- The proximal harvesting procedure of the plantaris tendon was reported in a clinical study of plantaris tendon autograft for lateral ligament reconstruction of chronic ankle instability. In 52 cases (93%), a strong 25- to 35-cm tendon graft was harvested. In one case (2%) the plantaris tendon was deemed too weak to serve as appropriate donor material. In three (5%) of 56 ankle reconstructions the plantaris tendon could not be located during surgery without preoperative imaging or ultrasound. This observation was consistent with incidence studies of the plantaris tendon in cadavers (absence ranged between 6% and 7%).

- Use of the distal approach to harvest the plantaris tendon also has been reported. Investigators failed to locate the plantaris tendon distally in 12% to 20% of cases in these studies.

COMPLICATIONS

- We have performed proximal plantaris harvesting in 102 cases with only one case of mild dysesthesia at a broadened scar. This did not create any functional deficits for the patient.
- Despite the close proximity of the saphenous nerve and vein, we have not observed any saphenous nerve or vein injuries.
- In 36 patients we have performed a distal approach plantaris harvest. Four of these patients (11% of cases) developed a hypertrophic or hypersensitive scar that created shoe irritation.

PEARLS AND PITFALLS

Indication

- We prefer the plantaris tendon over the peroneal tendons when grafting for chronic lateral ankle reconstruction. Use of this tendon will not further decrease dynamic control of lateral ankle instability.

Technique

- A proximal approach to a plantaris autograft will increase the success of the grafting procedure, because the distal tendon course is variable and may be difficult to find.
- A proximal approach to the plantaris tendon will reduce complications—making the incision at the calcaneal tuberosity could cause hypertrophic scarring and resultant shoe wear irritation.
- If the plantaris tendon cannot be located with distal harvesting technique, a small, medial, split Achilles tendon graft can be harvested with the tendon stripper advanced from distally to proximally.

REFERENCES

DEFINITION
- Peroneal tendon tears are a disruption of the fibers, most commonly of the peroneal brevis tendon.
- Acute tears rarely may be the result of an ankle fracture or severe sprain.
- The most common type of tear, an attrition tear, is the result of multiple subluxations or peroneal tendinitis.

ANATOMY
- The peroneus longus and peroneus brevis tendons both originate in the lateral compartment of the leg.
- The peroneus brevis inserts into the base of the fifth metatarsal and the longus into the proximal plantar first metatarsal and the first cuneiform.
- Both muscles are innervated by the superficial peroneal nerve.
- The peroneus longus courses posterior to the peroneus brevis tendon as they pass through the common peroneal synovial sheath proximal to the lateral malleolus.
- The superior peroneal retinaculum prevents subluxation of the peroneal tendons, forming a 1- to 2-cm fibrous sling from the posterolateral aspect of the distal fibula to the anterior Achilles sheath and lateral wall of the calcaneus.
- The inferior peroneal retinaculum covers the tendons 2 to 3 cm distal to the lateral malleolus.
- The peroneal tubercle of the calcaneus separates the peroneus longus and brevis into separate sheaths.

PATHOGENESIS
- Traumatic rupture may occur with ankle fractures or severe sprains but is rare.
- Partial longitudinal tears are commonly associated with peroneal tenosynovitis.
- Peroneus longus tears often are seen with a painful os peroneum, an enlarged peroneal tubercle, or pathology at the cuboid or calcaneus.
- Instability of peroneal tendons at the level of the superior peroneal retinaculum may be a cause of tendinitis leading to tears.
- Brevis tendon tears can be caused by compression between the lateral ridge of the malleolus and the peroneus longus tendon.
- Brevis tears are commonly at the level of the distal lateral malleolus.

NATURAL HISTORY
- Injury to the peroneal tendons is a frequently overlooked cause of persistent lateral ankle pain.
- There have been two mechanisms described by Munk and Davis leading to a tear of the peroneus brevis tendon.
  - Subluxation of the peroneus brevis tendon may occur as a result of chronic ankle instability, and the tearing of the superior peroneal retinaculum. The tendon may split as it subluxes over the sharp posterolateral edge of the fibula.
  - The second mechanism described is tearing of the brevis tendon caused by compression between the posterior fibula and the peroneus longus tendon.
- Peroneus longus tears, unlike peroneus brevis tears, are commonly seen at the level of the peroneal tubercle.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The evaluation of a patient with suspected peroneal pathology should start with a thorough history from the patient. Pain, swelling, and warmth may be caused by an acute injury or prolonged repetitive activity.
- The patient should be asked to pinpoint the area of pain to the examiner.
- Peroneus brevis tendon tears cause pain and persistent swelling along the peroneal tendon sheath and commonly behind the fibula.
- Peroneus longus tendon tears present with pain in the cuboid groove, in the plantar aspect of the foot, or at the level of the peroneal tubercle.
- Patients should be asked about other existing conditions. Rheumatoid arthritis, psoriasis, hyperparathyroidism, diabetic neuropathy, calcaneal fractures, and local injections have been associated with an increased risk of peroneal tendon tears.
- A history of subluxation or dislocation (FIG 1) can also give rise to peroneal tendon pathology.
- Physical examination of the peroneal tendons should include:
  - Assessment for posterolateral hindfoot swelling. Swelling indicates pathology; swelling about the lateral or posterolateral side of the ankle could represent tendinitis, tenosynovitis, repetitive subluxation, or tear.
  - Inspection for hindfoot alignment. Any varus position from neutral is a positive finding. Varus position is associated with an increased rate of peroneal tendon disorders.

FIG 1 • Dislocation of peroneal tendons.
Palpation along the course of the peroneal tendons should be performed to identify areas of tenderness. Any tenderness along tendons is a positive finding. Tenderness along the peroneal tendons may represent tendinitis, tenosynovitis, or tear.

Strength: ankle and foot eversion strength against resistance. Weakness in eversion is probably pathology, but near-normal eversion strength may not rule out peroneal pathology due to recruitment of other muscle groups. Strength may be decreased due to pain or tendon rupture.

Neurovascular assessment: sensory examination along the sural nerve distribution. Pain along the sural nerve distribution is assessed to rule out sural nerve neuritis.

Peroneal tunnel compression test. The foot is dorsiflexed and everted while manual pressure is applied along the retrofibular region. A positive finding (pain) indicates possible tendinitis, tenosynovitis, or tear.

Plantarflexion of the first ray. With the foot in neutral, active plantarflexion of the first ray is tested. Loss of plantarflexion of the first ray compared to the unaffected side is a positive sign. Loss or limitation of plantarflexion of the first ray is consistent with dysfunction of the peroneus longus tendon.

Testing for peroneal tendon dislocation or subluxation involves active rotation of the ankle, with subluxation or dislocation on palpation and visualization noted. Dislocation or subluxation gives rise to tendinitis or tears.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs and weight-bearing views of the ankle and foot are obtained. An axillary heel view will allow evaluation of the peroneal tubercle and the retromalleolar groove. Radiographs are important in ruling out fractures, arthrosis, tumors, and impingement.
- MRI is the study of choice when evaluating the peroneal tendons. Heterogeneity or discontinuity of the tendon, a fluid-filled tendon sheath, marrow edema along the lateral calcaneal wall, and a hypertrophied peroneal tubercle are all indications of peroneal tendon tears (FIG 2).
- Often the MRI underestimates the extent of pathology with regard to tears of the peroneus longus tendon. Peroneal tenography allows indirect visualization of the tendons by injecting contrast into the sheaths. Tenography may be useful to test for external compression, dislocation, and complete rupture.
- Ultrasound is noninvasive and does not expose the patient to radiation. Complete ruptures are seen as discontinuities in the tendon and partial tears are represented by focal lucencies. However, ultrasound has limited usefulness in imaging disorders of the peroneal tendons and is very dependent on the quality of the ultrasonographer.

**DIFFERENTIAL DIAGNOSIS**

- Sural nerve neuritis
- Calcaneus fractures
- Os peroneum fracture
- Lateral malleolar avulsion fractures
- Lateral ankle impingement
- Hypertrophic peroneal tubercle
- Bony spurring at the posterior lateral fibular groove of the calcaneus
- Prominent exostoses
- Hindfoot arthritis
- Tumor

**NONOPERATIVE MANAGEMENT**

- Nonoperative management consists of nonsteroidal anti-inflammatory medication, rest, activity modification, a lateral heel wedge, rarely use of an ankle-foot orthosis, and in difficult cases immobilization in a short-leg cast or walking boot for 6 weeks.
- Use of corticosteroid injections have been reported, but tendon splitting and rupture should be considered as possible complications of injection.

**SURGICAL MANAGEMENT**

- Redfern and Myerson describe an algorithm for surgical treatment, evaluating functional tendons, mobility of the remaining peroneal musculature, ankle stability, and position of the heel.
- After an MRI and clinical examination indicate a tear or rupture and the patient has failed to respond to conservative treatment, surgery is indicated.
- The procedure is finalized when intraoperative examination is performed.
- Upon gross examination three types of tears or ruptures are evaluated:
  - Type I: Both tendons are grossly intact.
  - Type II: One tendon is torn, the other usable.
  - Type III: Both tendons are torn and unusable.

**Preoperative Planning**

- All imaging studies are reviewed.
- MRI has been reported to both underestimate and overestimate the degree of tendon pathology.
- Operative planning should rest on the clinical evaluation, failure of conservative treatment, and occasionally injection of local anesthetic into the tendon sheath.
- Deformity of the hindfoot or laxity of the ankle ligaments that could cause recurrent tendon tears should be noted preoperatively and addressed in a single procedure with any peroneal tendon pathology.
Positioning
- The patient is positioned supine with a bump under the ipsilateral hip.
- A well-padded tourniquet is placed on the ipsilateral thigh.
- Blankets are used under the operative ankle to elevate the operative extremity.
- The contralateral leg is secured to the table with tape.

Approach
- Following the course of the peroneal tendons, a slightly curved 10-cm incision is made posterior to the lateral malleolus and carried distally along the course of the tendons.
- Blunt dissection is taken to the peroneal sheath, while protecting the sural nerve (FIG 3).

FIG 3 • Sural nerve position during approach.

TYPE I: BOTH TENDONS GROSSLY INTACT
- Perform the standard approach.
- Open the peroneal sheath in line with the tendons.
- Perform an intraoperative examination of the peroneal tendons to evaluate the amount of degeneration or tears (TECH FIG 1A).
- Perform a synovectomy, followed by removal of any degenerated tendon (TECH FIG 1B).
- If the remaining usable tendon is 50% or more of the original diameter, then a repair is indicated.
- Use a running 3-0 absorbable Vicryl suture to tubularize the tendon and return it to a smooth surface (TECH FIG 1C).
- Obtain hemostasis.
- Repair the sheath using 2-0 suture, followed by subcutaneous closure, and use nonabsorbable suture for the skin.

TYPE II: ONE TENDON TORN AND THE OTHER USABLE
- Perform the standard approach.
- Open the peroneal sheath in line with the tendons.
- Perform an intraoperative examination of the peroneal tendons to evaluate the amount of degeneration or tears.
- If one tendon is found to be more than 50% unusable, then a tenodesis is indicated.
- Perform the tenodesis side to side to the usable tendon proximal.7
- The sheath should remain open.
- Obtain hemostasis.
- Subcutaneous closure and use nonabsorbable suture for the skin.
Chapter 121 REPAIR OF PERONEAL TENDON TEARS

TYPE III: BOTH TENDONS TORN OR UNUSABLE
- Perform the standard approach.
- Open the peroneal sheath in line with the tendons.
- Perform an intraoperative examination of the peroneal tendons to evaluate the amount of degeneration or tears.
- In type III, both peroneal tendons are more than 50% degenerated or torn.
- Examine for excursion of the proximal muscle.
- If no excursion is present due to scarring and fibrosis, a tendon transfer is indicated.
- If excursion is present and the tissue bed is scarred, then a staged allograft with silicone rod is considered.
- If excursion is present and the tissue bed is free from scarring, then an onstage allograft or tendon transfer is considered.

PEARLS AND PITFALLS

| MRI | MRI has been shown to underestimate and overestimate the degree of peroneal tendon pathology compared with the intraoperative findings. It must be correlated with the clinical examination findings. |
| Intraoperative | The surgeon should be ready to evaluate the peroneal tendons during the procedure and proceed with the proper repair or reconstruction, as physical examination and current imaging findings have been described to both overestimate and underestimate the degree of pathology. |
| Intraoperative | The surgeon may need to resect a portion of the distal muscle belly of the peroneus brevis to make room in the peroneal sheath behind the fibula. |
| Intraoperative | The surgeon must evaluate the posterior fibula for an exostosis, which may be the cause of a peroneus brevis tear. |

POSTOPERATIVE CARE
- A posterior splint is applied in the operating room.
- At 1 week the splint is changed to a partial weight-bearing cast.
- At 3 weeks a wound check with suture removal is done, followed by a walking boot for 3 more weeks.
- At 6 weeks a prefabricated ankle brace is applied and active range-of-motion exercises are started.
- Physical therapy for calf strength is initiated at 6 weeks.
- Return to activities is considered at 3 months, with an orthotic containing lateral posting.

OUTCOMES
- A study by Redfern and Myerson assessed 29 feet with peroneus longus and brevis tears.
  - 31% had normal peroneal strength postoperatively, and
  - 59% had moderate peroneal strength.
  - 9% had postoperative complications.
  - 50% continued to experience some painful symptoms postoperatively; in all but three patients, pain was mild.

COMPLICATIONS
- Complex regional pain syndrome
- Adhesive tenosynovitis
- Failed repair

REFERENCES
Pathology of the peroneal tendons may cause chronic lateral ankle pain. Chronic lateral ankle pain can have many causes. Isolated tears of the peroneus brevis and longus are rare, but fissuring and longitudinal splitting of the brevis and longus tendons have been reported as a cause of chronic ankle pain and functional instability. Histologic evaluation of these splits has shown chronic wear with cystic and myxoid degeneration of the tendon. When recognized early, direct repair is possible with good results.

ANATOMY
- The peroneus brevis tendon can be identified at the level of the lateral malleolus since it is closest to the malleolus.
- The peroneus longus tendon is directly posterior to the brevis tendon.
- Both the longus and brevis tendons are tethered at the level of the lateral malleolus by the superior peroneal retinaculum, which is a band of deep fascia that extends from the tip of the lateral malleolus to the calcaneus.
- The tendons lie within the fibular groove; the most common location for longitudinal peroneus brevis tendon tears is at the fibular groove.
- The flexor hallucis longus tendon (FHL) has a strength percentage of 3.6 and can substitute for the peroneus brevis muscle–tendon unit, which has a strength percentage of 2.6.
- The FHL is an in-phase muscle with an axis of contracture similar to the peroneal muscle–tendon unit as it arises off the posterior fibula.
- This technique inserts the FHL into the residual stump of the peroneus brevis tendon.
- Our technique does not restore function of both peroneal tendons, since the distal portion of the peroneus longus tendon is too enmeshed in scar to serve as a viable insertion point for the FHL tendon.

PATHOGENESIS
- The pathogenesis of chronic peroneal tendon ruptures is unclear. Many theories have been suggested, including a zone of critical hypovascularity, mechanical impingement from the fibular groove, incompetence of the peroneal retinaculum, the presence of a sharp posterior fibular ridge, dynamic compression between the peroneus longus and brevis tendons, or the presence of a peroneus quartus muscle.

NATURAL HISTORY
- Patients typically present with advanced pathology of both tendons, such that neither can be salvaged in their entirety.

These patients tend to be middle-aged individuals who were active, working adults before their injuries. They will not wear bracing full-time or accept a surgical fusion of their hindfoot.
- Most patients have a history of at least one failed surgical procedure to attempt a primary repair or anastomosis of the peroneus brevis and longus tendons.
- The goal of this procedure is to provide dynamic stabilization of the ankle and restore the function of the peroneal tendons.

PATIENT HISTORY AND PHYSICAL FINDINGS
- These patients present with chronic lateral ankle pain and tenderness, swelling, and lateral ankle instability.
- Patients have considerable weakness and painful inversion and eversion compared with the contralateral limb.
- A fully functional FHL tendon must be demonstrated.
- Alignment of the affected lower extremity, including the hip, knee, ankle, hindfoot, and forefoot, must be assessed. A fixed hindfoot varus deformity may need to be corrected at the time of surgery.
- If mechanical instability of the ankle is present, a ligament reconstruction at the time of the first stage can be included.
- Muscle strength and balance should be evaluated, particularly inversion and eversion.
- The single heel rise is helpful to evaluate the normal inversion–varus alignment of the hindfoot.
- Manual muscle testing for FHL is helpful to evaluate the functionality and strength of the FHL motor unit.
- The anterior drawer test is used in evaluating the integrity of the anterior talofibular ligament and the calcaneofibular ligament.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Weight-bearing ankle and foot radiographs must be obtained.
- MRI of the involved ankle demonstrates chronic thickening, fissuring, scarring, and stenosis of the remaining peroneal structures. Tears in the substance of the tendon and fluid in the sheaths may also be visualized. Associated pathology of the ankle can be identified as well.

DIFFERENTIAL DIAGNOSIS
- Fibular fracture, stress fracture
- Peroneal tendon tear
- Ankle instability, involving the anterior talofibular ligament or calcaneofibular ligament
- Lateral process fracture of the talus
- Syndesmosis or subtalar sprains
- Impingement lesions
- Osteochondral lesions of the talus
- Tarsal coalition
NONOPERATIVE MANAGEMENT
- Functional rehabilitation includes range of motion for the ankle and hindfoot, concentric and eccentric muscle strengthening, endurance training with particular attention to the peroneal musculature, and proprioceptive training.
- Proprioceptive exercises improve dynamic stability and are an essential part of the rehabilitation program.
- Functional bracing or taping may be useful to help prevent recurrent injury during “at-risk” activities.

SURGICAL MANAGEMENT
- The technique is staged in two parts. During each stage, the patient is positioned in the same manner. Perioperative antibiotics are given. A pneumatic thigh tourniquet is applied as needed.

Preoperative Planning
- All imaging studies must be reviewed.
- Plain films must be reviewed for degenerative changes, malalignment, fractures, and the presence of hardware from previous surgeries.

Positioning
- The patient is placed supine on the operating table. Some prefer to place the patient on a beanbag and approach the lateral aspect of the ankle in a lazy lateral or lateral decubitus
position. We place saline bags under the ipsilateral hip to achieve this lazy lateral position.

**Approach**

- A longitudinal incision is centered over the course of the peroneal tendons, beginning 1 cm posterior and proximal to the tip of the fibula.

- The incision is extended to the base of the fifth metatarsal (FIG 4).
- Care must be taken to protect the sural nerve in the distal aspect of the incision, which is subcutaneous and just posterior to the incision.
- The surgeon carefully dissects through the extensive scar tissue (FIG 5).

**FIG 2** • Intraoperative photograph of a longitudinal peroneus brevis tear located in the fibular groove.

**FIG 3** • Axial T2 MRI image demonstrating (A) a tear in the peroneal tendon and (B) fluid around the sheath of the tendon.

**FIG 4** • Intraoperative photograph demonstrating the peroneal incision, from over the peroneals to the base of the fifth metatarsal.

**FIG 5** • Extensive scar tissue is evident overlying the peroneal tendons in this multiply operated patient.

**STAGE 1: DÉBRIDING THE PERONEAL TENDON AND SHEATH REMNANTS**

- If present, identify the peroneal sheath. Incise the sheath proximally through the superior peroneal retinaculum to the musculotendinous junction. Distally, open the sheath as far as needed.
- The first stage of reconstruction consists of débriding the remaining peroneal tendon tissue and the tendon sheath (TECH FIG 1).

**TECH FIG 1** • The peroneal tendon sheath and tendon are débrided.
STAGE 1: INSERTING THE HUNTER ROD

- Insert a 6-mm Hunter rod into the bed of the peroneal sheath. Suture the Hunter rod to the remaining stump of the peroneus brevis tendon distally with nonabsorbable suture. Proximally, the rod remains free in the sheath (TECH FIG 2).
- Trim the sheath of any redundancy and close it over the Hunter rod (TECH FIG 3).

TECH FIG 2 • A 6-mm Hunter rod is placed into the bed of the peroneal sheath. The Hunter rod is sutured into the remaining stump of the peroneus brevis tendon distally with nonabsorbable suture. Proximally, the rod remains free in the sheath.

TECH FIG 3 • The sheath is trimmed of any redundancy and closed over the Hunter rod.

STAGE 2: EXCHANGING THE HUNTER ROD FOR THE FHL TENDON

- With the FHL harvested, make a small incision at the proximal aspect of the previously made lateral incision overlying the proximal aspect of the Hunter rod, staying proximal to the lateral malleolus.
- Identify the FHL in the deep posterior compartment at its origin on the posterior fibula. Pull it into the lateral incision (TECH FIG 4).

TECH FIG 4 • After the flexor hallucis longus is released from the plantar surface of the foot, it is identified in the deep posterior compartment at its origin on the posterior fibula. It is then pulled into the lateral incision.
POSTOPERATIVE CARE

- Identify the proximal portion of the Hunter rod and attach the FHL to the proximal aspect of the Hunter rod.
- Make a small distal incision over the distal suture site of the Hunter rod and the remaining portion of the peroneus brevis (TECH FIG 5).

- Release the Hunter rod from this suture site and pull it distally, allowing the FHL tendon to slide into the newly formed tendon sheath.
- Attach the FHL to the remaining stump of the peroneus brevis tendon using a Pulvertaft weave (TECH FIG 6).

TECH FIG 5 • A small distal incision is made over the distal suture site of the Hunter rod and the remaining portion of the peroneus brevis.

TECH FIG 6 • The flexor hallucis longus is attached to the remaining stump of the peroneus brevis tendon using a Pulvertaft weave.

PEARLS AND PITFALLS

| Indication | Complete history and physical examination
| Address associated malalignment and pathology.
| For patients with chronic tendinosis of both peroneal tendons that have failed previous surgical repair
| Address additional pathology such as ligament instability or heel varus at the first stage of reconstruction.

| Incision | Avoid injury to the sural nerve. Preoperative testing is necessary to assess whether there is preexisting damage from the patient’s previous surgeries. By staying over the course of the peroneal tendons the surgeon can generally avoid the sural nerve as it sits about 1 cm posterior.

| Hunter rod placement | Use a nonabsorbable suture to attach the Hunter rod distally to avoid displacing the rod from the distal peroneus brevis stump.
| Perform adequate débridement on the peroneal tendons and surrounding scar.

| FHL harvest | Do not harvest the FDL.
| During exposure, be careful of the neurovascular structures.
| Tenodese the distal stump of the FHL to the FDL tendon with all five toes held in a neutral position.

POSTOPERATIVE CARE

- Postoperatively, after the insertion of the Hunter rod, patients are initially placed in a bulky Jones dressing for the first 2 weeks. Thereafter, they are allowed to bear weight as tolerated in a removable short-leg walking boot. They are instructed to remove the boot four times a day and perform active and passive range-of-motion exercises of the ankle and hindfoot in all planes of motion.
- Three months after the Hunter rod placement, the patient is brought back to the operating room for a transfer of the FHL tendon. Postoperatively, again, he or she is placed in a bulky Jones-type dressing for 2 weeks. Thereafter, the patient is advanced to a removable short-leg cast walker and maintained non-weight-bearing until 4 weeks. From week 4 to week 8, the patient is advanced to partial weight bearing in a removable cast walker. The patient is instructed to begin active and passive range-of-motion exercises of the ankle and hindfoot in all planes of motion. Home strengthening exercises are begun at 8 weeks, and the patient is advanced to an ankle stirrup at 12 to 14 weeks based on his or her strength. All patients are enrolled in formal physical therapy for functional rehabilitation of the ankle starting at 8 weeks.

OUTCOMES

- Data on the 8-year follow-up of seven patients has been published by the senior author (KLW). All wounds healed without complications. One workers’ compensation patient had continued pain and ambulates with a molded ankle-foot orthosis. The remaining six patients report complete relief of preoperative symptoms and a return to preinjury levels of activity. There were five excellent results, one good result, and one fair result.\textsuperscript{15,16}

COMPlications

- Wound complications
- Sural nerve injury
- Chronic pain
REFERENCES
DEFINITION
- Subluxation or dislocation of the peroneal tendon is a relatively uncommon injury, with the majority of the cases attributed to a traumatic event. Chronic subluxation has also been reported without any history of a specific event. Numerous surgical procedures have been described for the treatment of peroneal tendon subluxation, which may be classified into three categories: primary repair, soft tissue augmentation, and bony reconstruction. Primary repair of the superior peroneal retinaculum (SPR) is a commonly used surgical procedure. However, the effectiveness of primary repair depends upon the quality of the retinaculum and its ability to contain the peroneal tendons. When the SPR tissue is deficient or insufficient, then other procedures are necessary.

- Soft tissue procedures other than primary repair involve the augmentation of tissue already present or the rerouting of tissue from other structures to recreate the SPR.
- Bony procedures attempt to recreate a more stable fibular sulcus by deepening the fibular groove or extending the fibular rim. In this chapter we present a soft tissue augmentation procedure using a periosteal-based flap of the retrofibular sulcus.

ANATOMY
- Along the lateral aspect of the lower leg there are two muscles in the lateral compartment, the peroneus longus (PL) and peroneus brevis (PB). These two muscles arise at the proximal fibula and become tendinous before crossing the ankle.
- The peroneal tendons are contained in a single sheath located posterior and immediately distal to the fibula. Roughly at the level of the peroneal tubercle on the lateral calcaneus, the tendons separate into separate sheaths. The PB muscle belly extends more distal than the PL, and it becomes tendinous about 1.5 cm before the tip of the fibula. The PB tendon lies directly posterior to the fibula and anteromedial to the PL tendon as the two tendons course behind the fibula.
- The peroneal tendon sheath comprises the SPR, the calcaneofibular ligament (CFL), and the fibular sulcus. Respectively, the fibular sulcus represents the anterior border, the SPR the lateral border, portions of the SPR and CFL the posterior border, and portions of the CFL and posterior talofibular ligament the medial border of the peroneal tendon sheath. The PB inserts on the dorsal base of the fifth metatarsal, while the PL courses lateral to medial on the plantar aspect of the foot and inserts on the lateral sides of the base of the first metatarsal and medial cuneiform bones.
- The SPR is the primary restraint against subluxation of the peroneal tendons within the fibular groove. The SPR can have an extremely varied anatomy, with differences in width, thickness, and insertional patterns. Most commonly, the SPR inserts into both the Achilles tendon and the calcaneus. There is no distinct insertion point of the SPR; instead, it blends into the periosteum of the fibula.
- The anatomy of the fibula is varied as well. About 50% of fibulae have a bony ridge about 2 to 4 mm that augments the fibular sulcus. A cadaveric study by Edwards found that 82% of the time a sulcus was present at the posterior edge of the distal fibula. The average sulcus dimension was 3 mm deep and 6 mm wide. He found that 11% of the cadavers had no groove and that 7% of the cadavers had a convex fibula. A fibrocartilaginous rim was deficient in 48% of all cadavers and was absent in 30%.

PATHOGENESIS
- According to Zoellner and Clancy, in acute injury, the peroneal tendons tend to dislocate anteriorly over the lateral malleolus in people who have an anatomic predisposition. The fibular groove that serves as the pulley for the tendons can be shallow or convex, and the SPR may be absent or lax. A low-lying PB muscle belly can also cause subluxation (FIG 1). In a study of the effect of a low-lying PB muscle belly, Geller et al measured the location of the musculotendinous junction (MTJ) in 30 cadaveric specimens with respect to the fibula tip and peroneal tubercle, and also the width of the PB tendon.

FIG 1 • A, B. Anatomic dissection of a peroneus muscle belly that is too distal. Note the distance to the fibular tip.
The PB MTJ was significantly more distal and the tendons had a significantly greater diameter in torn (4/30) versus untorn (26/30) specimens (Table 1). The authors suggested that the location of the peroneus brevis MTJ may have an influence on the development of degenerative tears.

■ Recurrent dislocations are the result of an inciting acute traumatic episode of forceful ankle dorsiflexion with a simultaneous powerful contraction of the peroneal muscles that causes failure of the SPR. The dorsiflexion causes the SPR to tighten, thereby decreasing its diameter. This force is theorized to cause the retinaculum to be avulsed from its periosteal attachment. Eckert and Davis4 stated that the SPR’s attachment on the edge of the fibula does not adhere to a strong band of collagen, but instead blends into the periosteum of the lateral malleolus. They proposed that this weak insertion point is responsible for tendon dislocation secondary to avulsion of the fibular fibrocartilaginous lip and stripping of the SPR from the fibula.

■ The prototypical mechanism is in skiers as they forcefully contract the peroneal muscles to grab the ski edge into the snow.

■ Eckert and Davis4 classified SPR injury into three different grades according to severity:
  - Normally, the peroneal tendons are contained within the fibular sulcus by the SPR.
  - Grade 1 injury: Separation of the retinaculum from the cartilaginous lip and the lateral malleolus
  - Grade 2 injury: The distal 1- to 2-cm dense fibrous lip is elevated along with the SPR.
  - Grade 3 injury: Avulsion of a thin fragment of bone along with the collagenous lip attached to the deep surface of the SPR and deep fascia. (Radiographically, this may be represented by a “fleck sign.”)
  - In grade 1 injuries the peroneal tendons are easily reducible and are unstable under tension only.
  - In grade 2 and 3 injuries the peroneal tendons fail to remain reduced even without tension.

NATURAL HISTORY

■ Based on our experience, symptomatic recurrent subluxation does not resolve spontaneously.

■ Often, peroneal tendon dislocation continues to be misdiagnosed as a chronic ankle sprain. As the tendons dislocate and relocate, direct tendon injury occurs due to repetitive trauma.

■ Zone 1 tendon injuries occur at the fibular groove and usually involve the PB tendon. The action of the PB tendon snapping over the sharp ridge of the fibula leads to a longitudinal tear within the tendon substance (FIG 2).

■ Zone 2 injuries occur distal to the fibular tip, usually affecting the PL tendon. These injuries are caused by the PL coursing over the lateral wall of the calcaneus and turning 45 degrees at the cuboid facet. As the tears propagate, an inflammatory response may lead to tenosynovitis, tendinopathy, and potential tendon rupture. Peroneal tendon subluxation and dislocation is thought to accentuate the symptoms.

PATIENT HISTORY AND PHYSICAL FINDINGS

■ The patient may not be able to recall a traumatic event preceding the usual complaints of lateral ankle swelling and pain posterior to the lateral malleolus. Most patients report that the pain radiates proximally. Patients complain of persistent lateral ankle pain and swelling with a sensation of snapping or popping and may note a “pop” laterally before the tendon gives way.

■ On physical examination, the lateral ankle will be swollen and tender and may be ecchymotic in the acute setting. This can easily be confused with a lateral ankle sprain (Table 2), but the location of the pain may be used to differentiate between the two. Tenderness posterior to the fibula is indicative of peroneal tendinopathy; in contrast, tenderness at the anterior distal fibula suggests an anterior talofibular ligament injury (ankle sprain). However, since the CFL is the floor of the

peroneal tendon sheath, there may still be some confusion with more severe ankle sprains. A negative anterior drawer test and pain experienced when the foot is stressed against resisted eversion are more indicative of an injury to the SPR.

- Peroneal tendon subluxation test: In the prone position, with the knee flexed to 90 degrees, ankle dorsiflexion and forced hindfoot eversion against resistance is performed. Apprehension and peroneal tendon subluxation or dislocation with this provocative maneuver typically confirms the diagnosis.8

- Acutely dislocated peroneal tendons are occasionally seen on physical examination, but more commonly the tendons are reduced upon presentation and are dislocated only with the peroneal tendon subluxation test.

- Likewise, chronic peroneal tendon subluxation or dislocation may not present with the tendons frankly dislocated. Chronic subluxation and dislocation are generally best diagnosed by testing the ankle through a range of motion of inversion and plantarflexion to maximum eversion and dorsiflexion with resistance.

- Peroneal compression test: Direct compression of the peroneal tendon sheath to identify peroneal tendon injury

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standard weight-bearing ankle radiographs (AP, lateral, and mortise) define the bony ankle anatomy alignment. In cases of peroneal tendon subluxation, radiographs are usually negative. In a grade 3 injury a "fleck" of bone can be seen off the posterior distal fibula and is considered pathognomonic of an SPR injury (FIG 3).

- MRI affords detail of the soft tissues. Injury to the SPR, the peroneal tendons, or other supporting tissues may be identified: anomalous structures such as the peroneus quartus or a low-lying PB muscle belly may be suggested (FIG 4). A MRI is useful for preoperative planning, as other pathology (PB tear, low-lying MJT, fibular sulcus) may also need to be surgically addressed concomitant with repair of the subluxation or dislocating peroneal tendons. We also use MRI to define the morphology of the fibular sulcus. While MRI may identify dislocated or subluxated peroneal tendons, the tendons are often reduced while the patient is relaxed in the MRI scanner; however, occasionally dislocated tendons may be identified on axial MRI views.

**DIFFERENTIAL DIAGNOSIS**

- Injury to the lateral ligament complex
- Fracture of lateral malleolus, lateral process of the talus, anterior process of the calcaneus, or fracture at the base of the fifth metatarsal
- Osteochondral defect on the talar dome
- Peroneal tendon pathology

**NONOPERATIVE MANAGEMENT**

- Initial treatment of an acute injury consists of a well-molded, short-leg cast for 6 weeks. Successful outcomes of nonoperative management range from 14% in a study by Eckert and Davis4 to up to 56% as reported by McClennan,9 while other investigators have also reported variable outcomes in small case series.6,10,11,14 At best, only half of all patients become better. Therefore, as part of initial injury counseling, it is necessary to inform the patient that an operation will still be necessary, in most instances, despite conservative treatment. For patients with chronic subluxation, nonoperative treatment has not been shown to help; usually pain and symptoms recur once the short-leg cast is removed. In addition, more athletic, higher-demand patients tend to demand more reliable treatment and wish to proceed with operative repair.

**SURGICAL MANAGEMENT**

- Illustrated here is a modified surgical technique for soft tissue augmentation representing an alternative procedure for the treatment of peroneal tendon subluxation. No absolute contraindications exist for the procedure, but relative contraindications include:

  - The presence of a previous fracture or surgery that alters the local morphology and tissue quality
  - An Eckert and Davis grade 3 fracture, with a thin fragment of bone along the cartilaginous lip attached to the deep surface of the peroneal retinaculum; the anterior portion of
the SPR is already compromised and would not make a good surgical candidate.

- Patients with collagen disorders (Marfan, Ehlers-Danlos), where the strength and integrity of the periosteal flap could be suspect.

**Preoperative Planning**

- Routine ankle radiographs are essential to identify or rule out a rim fracture of the distal fibula, which occurs in 15% to 50% of all cases of peroneal subluxation.1

- Typically, the ankle radiographs appear normal. We routinely obtain an MRI to identify potential peroneal tendon tears, other soft tissue anomalies such as a peroneus quartus, or other causes of lateral ankle pain and instability that need to be addressed concomitant to SPR augmentation.13

- MRI axial cuts define the morphology of the fibular sulcus and are helpful in staging a bony procedure if necessary during the superior retinaculoplasty.

**Positioning**

- Either general or regional anesthesia is acceptable for this procedure, and the surgeon’s preference determines which anesthetic method to use.

- The patient is placed in an oblique lateral position using a beanbag or large support under the ipsilateral hip. Adequate rotation of the limb facilitates access to the posterior fibula.

- We routinely use a thigh tourniquet and carefully pad all bony prominences.

- An examination under anesthesia with provocative maneuvers such as the anterior drawer and rotary subluxation test may identify associated instability and locking or popping of the unstable peroneal tendons.

**Approach**

- The standard lateral approach is used.

- Care should be taken not to injure the sural nerve.

---

**SUPERIOR PERONEAL RETINACULOPLASTY**

- We use a standard lateral incision along the course of the peroneal tendons, taking care not to injure the sural nerve.

- Carry the incision down to the level of the peroneal tendon sheath (TECH FIG 1A).

- Inspect the SPR. Usually, it is attenuated and deficient, especially along its anterior border. The retinaculum often is lifted off its fibular attachment, thus allowing the peroneal tendons to subluxate.

- Make an incision in the peroneal sheath along the posterior border of the fibula.

**TECH FIG 1 • A.** Intraoperative photograph of a left ankle (lateral approach) shows the peroneal tendons subluxing anteriorly (brevis is the gray arrow, longus is the white arrow, superior peroneal retinaculum [SPR] is the black arrow). **B.** The peroneal tendons have been retracted anteriorly by the Penrose drain. Elevation of an anterior-based periosteal flap (outlined by dots) from the fibular groove has been completed. The black arrow shows the remnant of the SPR posteriorly. **C.** The tendons are relocated, after a groove-deepening procedure, into the recreated groove. The white dots outline the anteriorly based periosteal flap. It is then brought over to the posterior remnant of the SPR (black arrow). **D.** The flap is sutured to the remnant SPR with nonabsorbable sutures, completing the superior peroneal retinaculoplasty.
■ Retract the peroneal tendons anteriorly (TECH FIG 1B).
■ Occasionally, a small tear may be noticed in the PB tendon, warranting débridement or repair.
■ If a shallow or convex fibular groove is present, we typically perform a groove-deepening procedure.
■ We routinely reinforce the SPR with a soft tissue periosteal flap elevated from the fibular groove from a posterior to anterior direction.
■ Raise the periosteal flap, measuring about 1.0 × 3.0 cm, sharply, from posterior to anterior. After the flap is raised, a groove-deepening procedure may be performed when indicated.
■ Use a burr to deepen the groove 6 to 9 mm with all raw bony edges. The groove should extend from the fibular tip to 5 cm proximal. We use bone wax to smooth the groove.
■ Reduce the peroneal tendons and use the periosteal flap to contain the tendons, with the visceral side of the periosteum facing the tendons (TECH FIG 1C).
■ Suture the flap to the posterior remnant of the SPR with a series of 3-0 polybraided nonabsorbable sutures (TECH FIG 1D).
■ Range the ankle to evaluate the soft tissue repair, being sure that the tendons are free to move within the reconstructed peroneal tendon sheath.
■ Close the skin in usual fashion, and place the leg into appropriate dressings and splints with compressive bandages.

**DETAILED SURGICAL TECHNIQUE (COURTESY OF MARK E. EASLEY, MD, AND JAMES K. DEORIO, MD)**

**Positioning and Approach**
- Patient positioned in lateral decubitus position
- Regional anesthesia
- Thigh tourniquet
- Posterolateral approach
  - Immediately posterior to posterior margin of the distal fibula
  - Expose SPR.
  - Protect sural nerve.
  - Release SPR 1 to 2 mm posterior from posterior fibular margin.
  - Peroneal tendons will be dislocated, so determining exactly where to release SPR will be distorted.
  - Chronically dislocated tendon may be located in a “pocket” lateral to the distal fibula (TECH FIG 2).
  - Inspect the tendons, particularly the more anterior peroneus brevis, for a tear.
  - Peroneal tendon dislocations predispose the tendons to longitudinal split tears as the tendon repeatedly subluxates around the posterolateral fibula.

**TECH FIG 2** • Chronically dislocated peroneal tendons. **A.** Tendons in a pseudogroove on the lateral fibula. **B.** With peroneal tendons reduced, a “new gliding surface” and pocket of displaced superior peroneal retinaculum is evident.

**TRADITIONAL GROOVE-DEEPENING PROCEDURE (“TRAP DOOR TECHNIQUE”)**
- Creating the “trap door” in the posterior distal fibula
  - Maintain the peroneal tendons dislocated anteriorly to protect them during the fibular groove deepening.
  - Using a microsagittal saw, weaken the posterior cortex within the fibular groove (TECH FIG 3A).
  - While the fibula may be weakened only on the posterolateral margin, it is often necessary to weaken the “hinge” on the posteromedial margin as well (TECH FIG 3B).
  - The fibular groove also needs to be weakened transversely, at the proximal margin of the trap door (TECH FIG 3C).
  - Next, the trap door is completed at its distal margin, where the fibular groove rounds the distal fibula (TECH FIG 3D).
Elevate the trap door and reflect it posteriorly on its hinge (TECH FIG 3E,F). If the hinge should be separated completely, it is not a problem.

- Decancellate the distal fibula. We typically use a high-speed burr to evacuate the cancellous bone from the distal fibula (TECH FIG 4), but a curette may also be used.
- Replace the “trap door” into the deepened fibular groove.

- Impact the posterior fibular bone that was elevated, but try to preserve the smooth surface so that the peroneal tendons have a smooth gliding surface with little risk of impingement or creation of adhesions (TECH FIG 5A).
- The groove should be deep enough to keep the peroneal tendons reduced without manually restricting them (TECH FIG 5B). If it is not, then further decancellation may be necessary.

- Repair the SPR.
  - With the tendons reduced, repair the SPR by advancing the intact leading edge of the SPR from its posterior position to the posterolateral rim of the distal fibula from which the SPR was displaced by the tendon dislocation and elevated for the surgical exposure (TECH FIG 6A).
  - We routinely create drill holes in the distal posterolateral fibula to anchor the SPR (TECH FIG 6B).
  - Be sure that the tendons glide well within the new fibular groove and are not stenosed by the repair (TECH FIG 6C,D).

- Standard closure

**TECH FIG 3** • A. Weakening the posterolateral aspect of the fibula to create the “trap door.” B. Weakening the hinge of the trap door. C. Transverse osteotomy to ensure that the trap door can open. D–F. Elevating the trap door. D. Osteotome introduced into distal posterior fibula. E. Posterior fibula elevated at its posteromedial hinge. F. Trap door completely open.

**TECH FIG 4** • High-speed burr is used to remove cancellous bone from distal fibula.
MODIFIED TECHNIQUE USING A LARGE-DIAMETER DRILL BIT  (AS DESCRIBED BY ROBERT B. ANDERSON, MD)

- Chronically dislocated peroneal tendons may create a new pocket and even gliding surface on the lateral fibula (TECH FIG 7).
- Protect the dislocated tendons and adjacent soft tissues from the drill bit.
- From the distal fibular tip, introduce progressively larger-diameter drill bits to weaken the distal fibula and ream away the distal fibular cancellous bone (TECH FIG 8).
- While simple impaction of the posterior fibula to deepen the groove is possible at this point, we prefer to first weaken the cortex with a microsagittal saw as described for the traditional fibular groove-deepening procedure (TECH FIG 9A).
- To protect the smooth surface on the posterior fibula, a tamp can be placed longitudinally in the groove and impacted so as to avoid disruption of the smooth gliding surface for the peroneal tendons (TECH FIG 9B).
- The peroneal tendons should remain reduced without manually restraining them (TECH FIG 10A). If not, then deepen the groove further with a larger-diameter drill bit and perform further impaction of the posterior fibular surface.
- Reattach the SPR to the posterolateral fibular margin via drill holes.
- Be sure the peroneal tendons glide well without restriction in the deeper fibular groove (TECH FIG 10B).
- Standard closure
**TECH FIG 7** • Pseudogroove created on lateral fibula. **A.** Peroneal tendons lateral to fibula. **B.** With tendons reduced, the pseudogroove is visible, with the displaced and attenuated superior peroneal retinaculum.

**TECH FIG 8** • **A.** Drill bit introduced to decancellate the distal fibula. **B, C.** Fluoroscopic confirmation of proper drill bit position in distal fibula. **B.** AP view. **C.** Lateral view.

**TECH FIG 9** • Impaction of the posterior fibula to deepen the fibular groove. **A.** Weakening the posterolateral margin of the fibula to facilitate impaction. **B.** Using a tamp longitudinally to protect the gliding surface of the posterior fibula during its impaction.

**TECH FIG 10** • **A.** Peroneal tendons remaining reduced in the deepened fibular groove, even without superior peroneal retinaculum (SPR) repair. **B.** SPR repaired without stenosis of the peroneal tendons.
The peroneal tendons must be retracted anteriorly to allow visualization of the flap donor site to ensure sufficient harvest and to avoid damage to the peroneal tendons.
- The flap should maintain its continuity, anteriorly, with the fibrocartilage ridge. Use of a no. 69 Beaver blade is critical for flap elevation.
- The flap should be elevated before any groove-deepening procedure. If the groove is deepened before this, the periosteum will be destroyed.

</table>

POSTOPERATIVE CARE

- Postoperatively, the patient is immobilized in a short-leg cast and is kept non–weight-bearing for a total of 6 weeks.
- After 4 weeks the cast is removed and the patient is given a removable stiff-ankle rocker-bottom boot and remains non–weight-bearing for an additional 2 weeks while beginning physical therapy with ankle range-of-motion exercises.
- At the end of 6 weeks the patient is progressed to weight bearing as tolerated in the brace, after which the patient is weaned from the stiff-ankle boot and is started with ankle strengthening with inversion and eversion exercises.

OUTCOMES

- A favorable outcome of the procedure depends not only on how well the surgical procedure is performed but also on the appropriate treatment of other associated conditions. Often tendon injuries coexist with subluxation and dislocation and must be treated simultaneously. If tendon pathology such as a tear or degeneration is present and left untreated, pain may persist after surgery no matter how well the surgery was performed.
- In a preliminary study by Tan et al.\(^\text{15}\) conducted at two centers (University of Pennsylvania and University of Medicine and Dentistry of New Jersey), 10 patients with subluxation or dislocation of the peroneal tendons were treated with this technique. Nine of 10 patients had good to excellent results. One patient required a groove-deepening procedure.

COMPLICATIONS

- Peroneal tendon adhesions: Early range-of-motion exercises starting at 4 weeks can minimize this complication.
- Stenosing flexor tenosynovitis: Overtightening of the peroneal tendon sheath is unnecessary; the tendons simply need to remain reduced posterior to the fibula.
- Sural and superficial peroneal nerve injury

The editor and coauthors of this chapter wish to acknowledge the contribution of Dr. Enyi Okereke. Dr. Okereke passed away while on a medical mission to Enugu, Nigeria.

REFERENCES

DEFINITION
- Peroneal tendon subluxation or dislocation from the retrofibular groove is a rare cause of ankle pain and disability. The acute injury often remains unrecognized or is misdiagnosed as an ankle sprain.
- Untreated or misdiagnosed acute injury predisposes a patient to recurrent peroneal dislocation, potential peroneal tendon tear, or chronic dislocation.

ANATOMY
- The peroneus longus and brevis muscles are the two major structures within the lateral compartment of the leg, both arising from the proximal fibula (FIG 1).
- Both structures become tendinous before crossing the ankle joint and remain in a common sheath. As they course distally the tendon of the peroneus brevis lies against the posterior surface of the distal fibula, anterior and medial to the tendon of the peroneus longus.
- Distal to the fibula each tendon enters a distinct tendon sheath, separated by the peroneal tubercle.
- Posterior to the distal fibula both tendons are stabilized in the retrofibular groove by the superior peroneal retinaculum (SPR) (FIG 2).
- The posterior surface of the distal fibula is covered by a layer of fibrocartilage to allow smooth gliding of the peroneal tendons. The depth and width of the retrofibular (peroneal) groove is highly variable. A definite groove is present in about 80%. In the remaining cases the posterior surface of the fibula is flat or convex. A fibrocartilage rim on the lateral border of the fibula that adds an additional 2 to 4 mm to the depth of the sulcus is often present.
- The SPR, the primary restraint to peroneal instability, is composed of a band of the deep fascia that is continuous with the periosteum of the distal fibula but does not attach to the fibrocartilage rim or the posterolateral edge of the bone. It is extremely variable in width and thickness, and five distinct insertion patterns have been described, the most common being a band to both the Achilles tendon and the calcaneus. The fiber orientation of the SPR is parallel to those of the calcaneofibular ligament, and therefore inversion injuries of the calcaneofibular ligament may also cause injury to the SPR.

PATHOGENESIS
- Acute subluxation or dislocation of the peroneal tendons usually occurs while the foot is forcefully dorsiflexed with the peroneal muscles strongly contracted; it commonly occurs during a forward fall in Alpine skiing or in springboard diving.
- Resisted plantarflexion and inversion while the peroneals contract may also cause subluxation or dislocation of the peroneal tendons, and in this case it is commonly associated with lateral instability of the ankle.
Peroneal dislocation may also occur as a sequela to severe calcaneal fractures with lateral displacement of the calcaneus.\(^5,7\)

Peroneal dislocations can be classified into three grades depending on the pathoanatomy of the injury (FIG 3).

As a result of subluxation or dislocation, inherent injuries to the tendons can occur. Depending on the location of the tendon injury they are divided into zone I, II, and III.

- **Zone I** injuries are defined as those involving the fibular groove and most often affect the peroneus brevis tendon. As the tendons sublux in the groove, the brevis is forced onto the sharp posterolateral bony ridge of the distal fibula, causing a longitudinal split in the tendon from the strain of a 45-degree course change as well as compression by the overlying longus tendon.
- **Zone II** injuries are located between the tip of the fibula and the cuboid tunnel.
- **Zone III** injuries are located in the cuboid tunnel and primarily involve the peroneus longus tendon and possibly a painful os peroneum.

**NATURAL HISTORY**

- If diagnosed early, in acute peroneal dislocation the tendons can be manually reduced and held in a reduced position for a 4- to 6-week period of immobilization. In this situation, functional rehabilitation leads to maintenance of tendon reduction and complete recovery in about 50% of cases.\(^1\)
- With delayed diagnosis and treatment, recurrent subluxation and chronic dislocation is common and may lead to degeneration and tearing of the peroneal tendons.\(^9\)

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Most patients present well beyond the acute phase complaining of vague posterolateral ankle pain that radiates proximally with or without a popping sensation during activity.\(^12\)
- There may be a history of forced dorsiflexion trauma associated with a pop on the lateral aspect of the ankle.
- Often a history of an inversion–supination sprain and possible lateral ankle instability is reported.\(^10\)
- On physical examination peroneal tendinopathy is characterized as fullness along the tendons with diffuse tenderness. Localized tenderness over the posterior ridge of the fibula should raise suspicion for progression of the injury to a peroneal tendon split tear.
- Pain may be elicited with inversion stretch or active resisted eversion.
- Tendon subluxation typically presents as snapping or popping and pain with eversion against resistance. The peroneal tunnel compression test consists of having the patient perform this motion while palpating the posterior border of the fibula. Circumduction of the ankle may demonstrate dislocation of the tendons with eversion and dorsiflexion and spontaneous relocation with plantarflexion and inversion (FIG 4).
- Chronic dislocation of the tendons is characterized by a palpable ridge over the lateral distal fibula often associated with chronic swelling.
- Eversion strength may be limited by pain. Significant weakness of active eversion without much pain should raise suspicion for a complete tear of the peroneal tendons.

**FIG 2** • Superior view of the ankle region shows the relationship of the fibular groove, superior peroneal retinaculum, peroneal tendons, and cartilaginous ridge. (From Coughlin MJ, Mann RA, eds. Surgery of the Foot and Ankle, 7th ed. St. Louis, MO: Mosby, 1999, p. 819.)

A complete examination of the ankle should also include evaluation of associated injuries ruling out differential diagnoses. This includes (but is not limited to) the following:
- Lateral ankle instability: history of frequent sprains, cavovarus foot, increased laxity with anterior drawer or inversion stress test compared to the contralateral side
- High ankle sprain (syndesmotic sprain): pain over anterior ankle syndesmosis, pain with provocative maneuvers (calf squeeze test, external rotation stress test)
- Painful os trigonum or posterior talar process fracture: pain with forced plantarflexion, pain with resisted plantarflexion of the great toe

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs including AP, mortise, and lateral views of the ankle should be obtained to rule out fracture or large osteochondral defects of the talus.
- Occasionally a “fleck” sign, an avulsion fracture off the posterior distal fibula, can be seen on AP or mortise views. If present this is considered pathognomonic for a grade III injury to the SPR with peroneal dislocation.4 As shown in FIGURE 5A, this may be difficult to see without the use of a “hot lamp.”
- Stress views may be helpful to rule out lateral ankle instability.
- CT may be helpful in uncertain diagnosis to evaluate the anatomy of the fibular groove and detect small avulsion fractures, which may be difficult to see on plain films. Axial CT scan images may also confirm peroneal tendon dislocation.
- MRI can identify injury to the SPR, subluxated or dislocated tendons, and intrasubstance degeneration and split tears of the tendons (FIG 6).
- Ultrasound, while operator-dependent, allows a dynamic, real-time examination to evaluate subluxation during provocative maneuvers.

DIFFERENTIAL DIAGNOSIS
- Peroneal tendinopathy or tears
- Lateral ankle instability
- High ankle sprain
- Osteochondral defect of the talus
- Painful os trigonum or posterior talar process fracture
- Retrocalcaneal bursitis

NONOPERATIVE MANAGEMENT
- Acute peroneal subluxation or dislocation can be treated nonoperatively if the peroneal tendons can be reduced and held in a reduced position.
- In this case treatment consists of short-leg cast immobilization in slight plantarflexion and inversion for 4 to 6 weeks, followed by functional rehabilitation. U- or J-shaped foam or felt pads can be placed in the cast to apply pressure around the distal fibula and maintain the position of the peroneal tendons.
- In our opinion, there is no role for nonoperative treatment for symptomatic chronic peroneal dislocation or recurrent subluxation.

SURGICAL MANAGEMENT
- All irreducible peroneal tendon dislocations and those associated with a rim avulsion fibular fracture should be considered for acute surgical reduction and repair.
- Operative treatment is also indicated for all chronic injuries in patients with pain or functional limitations.
- Five basic categories of repair have been described: (1) anatomic reattachment of the retinaculum, (2) bone block procedures, (3) reinforcement of the superior peroneal retinaculum with local tissue transfers, (4) rerouting of the tendons behind the calcaneofibular ligament, and (5) groove-deepening procedures.8
- The goal of groove-deepening procedures is to increase the height of the posterolateral fibular rim to prevent the peroneal tendons from subluxating.
General contraindications to surgical intervention include peripheral vascular disease, skin breakdown or vasculitis, and patients who are “voluntary” subluxators. These are usually patients with generalized ligamentous laxity. Physical examination usually shows the peroneal tendons to subluxate to the lateral rim of the fibular on both ankles, but not over it.

Preoperative Planning

- We recommend reviewing all imaging studies preoperatively to plan for not only fibular groove deepening but also any procedures to address associated pathology. Plain films should be reviewed for fractures, loose bodies, ankle and foot alignment, and the presence of any hardware (from previous procedures).
- Associated fractures, osteochondral lesions, and lateral ankle instability should be addressed concurrently.
- We routinely perform an examination under anesthesia on the operating table before making an incision to assess the ankle and subtalar joint. The peroneal tendons may also be assessed under anesthesia, but without the patient being able to evert against resistance, this is of limited value.

Positioning

- The procedure is performed with the patient in the semilateral position (FIG 7). A bean bag is used to maintain the position of the body with a 10-lb sandbag underneath the ipsilateral hip. This allows the physician to readily access the posterior fibula and obtain fluoroscopic AP and lateral ankle views of the ankle without moving the C-arm from the standard AP position. Regional or general anesthesia may be used and a thigh tourniquet is applied.

Approach

- The standard surgical approach is through a longitudinal, curvilinear incision on the posterior aspect of the fibular following the course of the peroneal tendons to roughly the level of the peroneal tubercle (FIG 7).
- This allows excellent visualization of the SPR, the peroneal tendons, and the posterior aspect of the distal fibula and also provides sufficient access to the lateral tibiotalar joint in cases where concomitant lateral ligament reconstruction is indicated.
- If lateral ankle instability and injury to the peroneal tendons distally have been ruled out preoperatively or with the examination under anesthesia, the approach can be limited to a longitudinal incision just posterior to the fibula.

FIG 6 • T1-weighted (A) and T2-weighted (B) axial MRI images showing dislocated peroneal tendons (arrow) with abundant tenosynovitis. Note the shallow retrofibular groove and the torn superior peroneal retinaculum.

FIG 7 • Utilitarian posterolateral approach for peroneal repair and indirect fibular groove deepening.

INDIRECT FIBULAR GROOVE DEEPENING

- Make a curvilinear incision along the posterior aspect of the distal fibula. It extends toward the base of the fifth metatarsal but usually ends at the level of the peroneal tubercle.
- Develop full-thickness skin flaps to avoid skin necrosis.
- Protect the sural nerve and branches of the superficial peroneal nerve.
- Incise the peroneal sheath distal to the fibula. If the SPR is still intact, incise it over the bone and then sharply elevate it off the fibula, leaving a cuff of tissue on the distal fibula. Retract the edges of the SPR posteriorly with two small hemostats to facilitate later repair.
- Inspect the peroneal tendons, excise inflamed tenosynovium, and débride and repair split tears in the tendons with buried nonabsorbable suture (TECH FIG 1A,B).
- Excise any low-lying peroneus brevis muscle from the tendon. Also excise a normal anatomic variant, the peroneus quartus, a supernumerary muscle of the lateral compartment of the leg, if present. These additional procedures tend to make room in the groove for the peroneal tendons (TECH FIG 1C).
- Expose the distal fibular tip, avoiding injury to the calcaneofibular ligament.
Place an intramedullary guide pin from distal to proximal inside the fibula, in line with the posterior cortex (TECH FIG 2A). Thin the posterior cortex by sequential reaming over the guidewire (usually 7 to 8 mm) (TECH FIGS 2B AND 3). We routinely use suitably sized reamers from the biotenodesis screw system (Arthrex, Naples, FL) or any anterior cruciate ligament instrument set. Alternatively, consider using progressively larger drill bits from a standard trauma set or cannulated drills from a dedicated fifth metatarsal (Jones fracture) set (Wright Medical, Memphis, TN).

**TECH FIG 1** • **A.** The superior peroneal retinaculum is incised longitudinally and retracted with two hemostats. A longitudinal split tear of the peroneus brevis tendon (PBT) is often identified in chronic dislocations. **PLT,** peroneus longus tendon. **B.** Split tears of the PBT are débrided or repaired. **C.** The low-lying peroneus brevis muscle and if present the peroneus quartus (PQT) are excised to create room for the peroneal tendons.

**TECH FIG 2** • **A.** An intramedullary guide pin is placed into the distal fibula parallel to the posterior cortex. **B.** The posterior cortex of the fibula is thinned by intramedullary reaming with cannulated reamers over the guide pin. **C.** To avoid fracture of the edge of the fibula during impaction the posterolateral cortex is perforated with an osteotome (this is necessary only in very hard bone). **D.** The posterior cortex of the fibula is impacted into the void created by the reamers with an appropriate-size tamp.
Once the posterior cortex is sufficiently thinned, impact it into the void created by the reamers using an appropriately sized bone tamp (TECH FIGS 2D AND 3). This preserves the physiologic gliding surface covering the groove, making it a smooth bed for tendon excursion. If the bone is very hard and impaction cannot be performed easily, the posterolateral cortex of the fibula can be perforated with an osteotome or microsagittal saw to facilitate impaction of the posterior cortex (TECH FIG 2C).

- Also tamp the very distal tip of the fibula inward to avoid a sharp edge that would otherwise impinge on the peroneal tendon as it courses into the foot.
- When done correctly the entire peroneus brevis and at least 50% of the peroneus longus tendon should be covered by the fibular rim with the tendons in a resting position.
- After completing groove deepening, tendon débridement, and tendon repair, repair the SPR.
- Sharply elevate the remainder of the cuff on the fibula off bone, exposing the lateral cortex, which is then roughened to bleeding bone with a rasp or rongeur.
- Excise any redundant SPR tissue and advance the remaining SPR to the previously prepared cortical bed; secure it through either drill holes or suture anchors.
- Place three or four drill holes or suture anchors about 1 cm apart proximally from the tip of the fibula (TECH FIG 4A). Reattach the posterior flap of the SPR to the prepared bone with 2-0 suture in a “pants-over-vest” technique, making sure that the space between the bony surface of the lateral malleolus and the SPR is obliterated. Suture the anterior portion of the retinaculum over the repair with interrupted 2-0 suture (TECH FIG 4B,C).

- Test the stability of the repair by ranging the ankle through a full range of motion. Verify free excursion of reduced tendons; the tendons should not be trapped by the repair. Overtightening of the SPR repair is not necessary; the goal is to keep the peroneal tendons reduced posterior to the fibula.
PEARLS AND PITFALLS

- Avoid surgery on voluntary dislocators.
- Maintain the operated limb in a semilateral position (use a large bump under the ipsilateral hip or a bean bag).
- Incise the SPR on the posterior margin of the fibula, not too far posteriorly.
- Create adequate room for the peroneal tendons.
- Inspect both peroneal tendons for tears.
- Avoid fibular stress fracture.
- Avoid creating stenosis of the peroneal tendons when repairing the SPR.

- High risk of recurrence
- It is difficult to gain access to the posterior aspect of the fibula with the patient in a supine position.
- This allows excision of redundant tissue and a secure SPR repair to bone.
- Excise all low-lying peroneus brevis muscle and the entire peroneus quartus if present.
- Débride and repair as necessary.
- Reaming the fibula may not weaken the posterior fibula adequately, particularly in young, healthy patients with good bone quality.
- Observe satisfactory tendon excursion with ankle and hindfoot range of motion after SPR repair.

POSTOPERATIVE CARE

- Immediately postoperatively the leg and ankle are placed into a posterior and U-splint in neutral position and the patient is kept non-weight-bearing for 2 weeks.
- Sutures are removed at 2 weeks. A short-leg walking cast is applied and the patient is allowed to bear weight as tolerated.
- At 6 weeks the cast is removed and a cam walker boot is applied to avoid ankle inversion, while allowing plantarflexion and dorsiflexion. Active range-of-motion exercises are initiated at that time.
- Peroneal strengthening is started at about 8 to 10 weeks after surgery.
- Full return to activities is expected between 4 and 6 months postoperatively.
- In elite athletes, given a stable reconstruction, we have been more aggressive with the rehabilitation, to include biking and pool activities by 4 weeks.

OUTCOMES

- As many variations of fibular groove-deepening techniques have been described, all reported results in the literature are derived from small retrospective series. There are no published prospective randomized studies comparing different surgical techniques.
- In general, results of fibular groove-deepening techniques have been good, as long as the underlying pathology is correctly addressed.8
- In our hands, indirect grooving has provided excellent overall results while minimizing the surgical dissection and morbidity. We have not had recurrent dislocations using this technique.
- We recommend that fibular groove deepening should be performed with every SPR reconstruction for chronic peroneal dislocation.

COMPLICATIONS

- Infection
- Delayed wound healing
- Sural nerve injury
- Recurrent dislocation
- Loss of motion

REFERENCES

Tibialis anterior rupture may present as an acute injury or as a chronic painless foot drop. The diagnosis is often delayed. Recommended treatment is surgical for active patients and nonsurgical for low-demand patients. Surgical options include direct repair and reconstruction.

**ANATOMY**
- The tibialis anterior muscle originates from the lateral tibial condyle and interosseous membrane.
- Its insertion is the medial side of the medial cuneiform and the inferomedial base of the first metatarsal.
- The musculotendinous junction is at the junction of the middle and distal thirds of the tibia.
- The tendon courses within a synovial sheath from the musculotendinous junction to its insertion, deep to the extensor retinaculum of the ankle and foot.
- Innervation is the deep peroneal nerve.
- The tibialis anterior muscle controls deceleration of the foot after heel strike and dorsiflexes the ankle.

**PATHOGENESIS**
- Younger individuals with healthy tibialis anterior tendons rarely suffer spontaneous rupture; instead, their mechanism of injury is laceration from penetrating trauma or distal tibia fracture.
- Spontaneous ruptures typically occur in older individuals with degenerative tendinopathy of the tibialis anterior tendon. Minor trauma may be associated with these ruptures, with a mechanism of plantarflexion–eversion. Ruptures typically occur within 3 cm of the tendon’s insertion on the medial cuneiform.

**NATURAL HISTORY**
- The natural history of tibialis anterior rupture is inferred from studies documenting the results of nonoperatively treated patients. These patients will ambulate with a slap-foot gait and sometimes have difficulty negotiating uneven terrain. Most patients are functional; however, they may require a brace.
- Nonoperatively treated patients tend to be older and lower-demand. The natural history for younger, more active patients may indicate less desirable results.
- Definite conclusions regarding the natural history of tibialis anterior ruptures are limited due to the low number of reported cases in the literature and lack of natural history studies.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- Physical examination methods include:
  - Examining for swelling. The examiner should palpate along the course of the tibialis anterior muscle–tendon. Swelling with discontinuity of the tendon indicates a tendon rupture. An anterior ankle mass may be the presenting complaint.
  - Gait disturbance. The examiner should observe the patient ambulating, looking for slap-foot gait or foot drop. Chronic ruptures may present with minimal gait disturbance; the patient may have difficulty ambulating only when on uneven surfaces. Inability to heel-walk indicates tibialis anterior dysfunction. The patient may need to hyperflex the hip and knee to clear the foot during the swing phase of gait, since the ankle does not dorsiflex adequately.
  - Muscle strength is evaluated with manual motor testing. No contraction or weak ankle dorsiflexion suggests tibialis anterior dysfunction. Patients will substitute the toe extendors for the tibialis anterior during ankle dorsiflexion, exhibiting toe hyperextension when asked to dorsiflex the ankle.
  - The examiner should note any heel cord tightness. Subacute and chronic injuries often present with heel cord contractures, since the major antagonist to ankle plantarflexion is forfeited with tibialis anterior tendon rupture. As a rule, at least 10 degrees of ankle dorsiflexion must be present for a tibialis anterior repair or reconstruction, and thus surgical management may require adding Achilles tendon or gastrocnemius lengthening.
  - The examiner should completely assess the involved extremity to rule out other diagnoses. The most common errors in diagnosis are:
    - Lumbar radiculopathy: presents with diminished sensation, positive straight-leg raise test
    - Peroneal nerve palsy: affects the toe extendors and peroneal musculature in addition to the tibialis anterior. Preservation of extensor hallucis longus and toe extensor function will distinguish tibialis anterior rupture from peroneal nerve palsy.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Imaging studies are generally not required in the evaluation of tibialis anterior tendon ruptures, since the diagnosis is usually simple to make on clinical examination alone.
- Radiographs are nondiagnostic and rarely required in the evaluation of tibialis anterior tendon ruptures. Radiographs are, however, useful to assess associated injuries (tibia fractures).
- MRI may be useful in chronic cases where patients do not recall a history of trauma. MRI demonstrates lack of continuity in the tibialis anterior and signal change in the tendon, particularly with pre-existing tendinopathy. Because the tibialis anterior tendon courses from lateral to medial across the anterior ankle and retracts with rupture, occasionally it is difficult to assess.
- If there is uncertainty in the diagnosis, electrodiagnostic studies may identify common peroneal palsy or lumbar radiculopathy.

**DIFFERENTIAL DIAGNOSIS**
- Peroneal nerve palsy
- Lumbar radiculopathy
- Rarely, a peripheral neuropathy may present as isolated tibialis anterior tendon dysfunction.
NONOPERATIVE MANAGEMENT

- Low-demand patients may be treated with an ankle–foot orthosis (AFO).

SURGICAL MANAGEMENT

- Direct repair of the tendon is occasionally possible, but delay in diagnosis may preclude direct repair due to muscle contracture.
- A sliding tibialis anterior tendon grafting technique has been described to gain tendon length to allow repair, and allograft tendon transfers have been proposed in the absence of tibialis anterior myofibrosis.
- Our preferred reconstruction for tendons that cannot be directly repaired is to augment the repair with the adjacent, native extensor hallucis longus (EHL) tendon (FIG 1).

Preoperative Planning

- Imaging studies are reviewed when available to appreciate the extent of pre-existing tendinopathy and to potentially identify the approximate site of the rupture.
- The surgeon should prepare for Achilles tendon lengthening or gastrocnemius–soleus recession to achieve adequate (at least 10 degrees) dorsiflexion.

Positioning

- The patient is positioned supine. A bump may be placed under the ipsilateral hip, but this is typically not necessary since access is required only to the anteromedial ankle.

Approach

- An anterior approach is made directly over the course of the tibialis anterior tendon.
- As has been learned from total ankle arthroplasty and open reduction and internal fixation of tibial pilon fractures, careful soft tissue handling is essential.

EXTENSOR HALLUCIS LONGUS TRANSFER TO MEDIAL CUNEIFORM

- Perform gastrocnemius recession or Achilles tendon lengthening if indicated.
- Use an anterior approach with an incision over the course of the tibialis anterior tendon (TECH FIG 1A,B).
- Divide the superior and inferior extensor retinaculum and tibialis anterior sheath.
- Isolate the remnant of the tibialis anterior tendon. Occasionally direct repair is possible, rarely by advancing the residual tendon to bone, but instead to the residual tendon stump on the medial cuneiform. If inadequate tendon is available or muscle excursion is poor, then proceed with EHL transfer.
- Expose the EHL tendon. Proximally the EHL is in a separate sheath adjacent to the tibialis anterior.
- Through a separate 3- to 5-cm incision over the distal EHL immediately proximal to the first metatarsophalangeal joint, divide the EHL tendon distally. Leave enough distal stump to suture to the adjacent tendon of the extensor hallucis brevis. Place a whipstitch consisting of no. 2 non-absorbable suture in the free end of the EHL.
- Pass the EHL under the skin bridge and through the tibialis anterior sheath proximally. The EHL will now occupy the previous sheath for the tibialis anterior (TECH FIG 1C,D).
- Drill a vertical hole in the medial cuneiform for attachment of the EHL. Sequentially drill using 2.5-mm, 3.5-mm, and 4.5-mm drill bits. Enlarge the hole with a
The tendon sheath is opened, exposing the torn retracted end of the tibialis anterior. The sheath is carefully preserved for later repair. The extensor hallucis longus (EHL) tendon is harvested by dividing it at the level of the metatarsophalangeal joint. The EHL tendon sheath is entered proximally. The EHL tendon is passed into the tibialis anterior sheath and pulled distally. A drill hole is placed from dorsal to plantar at the midpoint of the medial cuneiform. The drill hole is sequentially enlarged. Fixation using a biotenodesis screw (Arthrex, Naples, FL). The graft is also looped around the medial cuneiform and sutured to itself and surrounding soft tissue. Proximally, the EHL is tenodesed to the tibialis anterior stump. The EHL stump is sutured to the extensor hallucis brevis. The tibialis anterior sheath is closed.
curette as needed to allow graft passage. Leave enough periosteum to provide additional points of attachment for suturing the graft in place.

- Secure the graft with the ankle in 10 degrees of dorsiflexion (TECH FIG 1E–H).
- Pass the EHL graft from dorsal to plantar. Fixation may be accomplished with an interference screw or by looping the graft around the medial cuneiform and suturing it to surrounding periosteum and back on itself. The EHL tendon may be further anchored to the residual distal fibers of the torn tibialis anterior tendon.
- The transferred EHL tendon serves to bridge the gap created by the tibialis tendon rupture. However, the relative strength of the EHL muscle is far less than that of the tibialis anterior muscle. Therefore, in the absence of myofibrosis of the tibialis anterior, we recommend sewing the residual tibialis anterior tendon stump to the transferred EHL tendon under some tension.
- Attach the distal EHL stump to the extensor hallucis brevis, and we recommend dorsiflexing the hallux about 10 to 15 degrees to compensate for anticipated stretching of this tendon transfer postoperatively (TECH FIG 1I).
- Close the tibialis anterior tendon sheath, superior extensor retinaculum, and wound in layers (TECH FIG 1J).
- Place a splint or bivalved cast with the ankle in 10 degrees of dorsiflexion. Avoid plantarflexion as this places tension on the wound edges and tendon transfer.

### Pearls and Pitfalls

<table>
<thead>
<tr>
<th>Misdiagnosis</th>
<th>Perform a complete history and physical examination to rule out conditions that may mimic tibialis anterior rupture.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Failure to address heel cord tightness</td>
<td>Note ankle dorsiflexion as part of the preoperative evaluation and perform Achilles tendon lengthening or gastrocnemius recession as indicated.</td>
</tr>
<tr>
<td>Inadequate EHL graft length</td>
<td>Expose and divide the distal end of the EHL at the metatarsophalangeal joint level.</td>
</tr>
<tr>
<td>Wound breakdown</td>
<td>Carefully close the tibialis anterior sheath, superior extensor retinaculum, and subcutaneous tissue before skin closure. Immobilization in at least 5 degrees of dorsiflexion is important to avoid tension on the wound edges.</td>
</tr>
<tr>
<td>Graft failure</td>
<td>Secure fixation with proper use of an interference screw and adequate graft length to suture back on itself and surrounding tissues. Postoperative immobilization. Avoidance of early aggressive rehabilitation.</td>
</tr>
</tbody>
</table>

### Postoperative Care

- A short-leg cast is worn for 6 weeks, followed by an ankle-foot orthosis (AFO) for an additional 6 weeks.

### Outcomes

- Sammarco et al. presented a series of 18 patients with acute and chronic tibialis anterior tendon ruptures managed with direct repair or interpositional graft. There was significant improvement in the average hindfoot score. The authors concluded that surgical repair of a ruptured tibialis anterior tendon can be beneficial regardless of age, sex, medical comorbidities, or delay in diagnosis.
- Ouzounian et al. reported on seven patients with tibialis anterior rupture treated with a variety of surgical reconstructive techniques. All patients had an increase in strength and function.
- Markarian et al. failed to show a significant difference between operative and nonoperatively treated groups. The lack of statistical significance was possibly due to the bimodal age distribution in the study, with older, more sedentary patients receiving nonoperative treatment.
- The literature is scarce regarding the results and complications of surgical reconstruction of the tibialis anterior tendon due to the rarity of this injury.

### Complications

- Intraoperative graft complications
- Neuroma
- Wound dehiscence
- Infection
- Graft failure

### References

DEFINITION
- Pathology leading to a spectrum of motor function loss that includes loss of ankle dorsiflexion
  - Common peroneal nerve palsy, L5 radiculopathy, cerebrovascular accident
  - Loss of ankle dorsiflexion and hindfoot eversion
  - Retained posterior tibial tendon (PTT) function
- Hereditary sensory motor neuropathy
  - A constellation of motor function deficits and associated deformity
  - Includes loss of dorsiflexion and hindfoot eversion
  - Retained PTT function
- Flaccid paralysis
  - Global loss of motor function to the ankle and foot

ANATOMY
- Posterior tibialis
  - Muscle originates on the posterior tibia, interosseous membrane, and fibula.
  - Muscle and then tendon course in the deep posterior compartment.
  - Tendon travels directly posterior to the medial malleolus.
  - Tendon has numerous insertions on bones of plantar midfoot, spring ligament, and medial aspect of navicular.
- Interosseous membrane (IOM) and distal tibia–fibula syndesmosis
  - Thick fibrous bands between tibia and fibula
  - Distal tibia–fibula syndesmosis is narrow, with little space for tendon transfer even when a generous window is created in the distal IOM.
- Inferior extensor retinaculum
  - On the dorsum of the foot to prevent bowstringing of the extensor tendons as they transition across the anterior ankle to the dorsal foot
- Sciatic nerve
  - Comprises tibial and common peroneal nerves that separate immediately proximal to the popliteal fossa
  - Common peroneal nerve often affected in these neuropathies
- Superficial peroneal nerve
  - Motor function to anterior and lateral compartment muscles
    - Dorsiflexion and eversion, respectively
  - Sensory distribution to dorsum of the foot
- Deep peroneal nerve
  - Courses between tibialis anterior and extensor hallucis longus tendons proximal to the ankle
  - Located directly on the dorsum of midfoot
  - Immediately deep to extensor hallucis brevis muscle belly
  - Motor function to intrinsic muscles of foot
  - Sensory distribution to first web space
- Tibial nerve function typically spared
- Tibial nerve must be intact to create a dynamic tendon transfer
- If tibial nerve is not intact, then transfer can only be a tenodesis
- Anterior ankle and dorsal midfoot neurovascular structures at risk
  - Superficial peroneal nerve (may be insensate as part of the neuropathy)
  - Deep neurovascular bundle
    - Anterior tibial artery
    - Deep peroneal nerve (may also be insensate as part of the neuropathy)
    - Peroneal artery branch
    - Situated directly on anterior distal IOM

PATHOGENESIS
- Loss of common peroneal nerve function
- Loss of ankle dorsiflexion and hindfoot eversion
- Loss of major antagonists
  - Eventual equinus contracture
    - Imbalance of hindfoot inverter (PTT) and everters (peroneus brevis) and usually, but not always, peroneus longus
  - Eventual hindfoot varus deformity
    - Imbalance of hindfoot inverters (PTT) and everter (peroneus longus)
- Flaccid paralysis
  - Tibial and common peroneal nerve palsies
  - No motor function distal to knee
  - Since both sets of major antagonists lost, typically no contractures

NATURAL HISTORY
- Foot drop may eventually recover.
  - Tendon transfers should not be considered until a chance for recovery has been ruled out.
- Common peroneal nerve palsy may lead to progressively worsening equinocavovarus foot deformity due to overpull of plantarflexors and inverters powered by intact tibial nerve and loss of dorsiflexors and everters powered by compromised common peroneal nerve.
- Flaccid paralysis remains relatively stable since both sets of antagonists are compromised.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Gait abnormality
  - “Slap foot gait”
    - Inability to dorsiflex ankle and control tibialis anterior from heel strike to stance phase
  - Exaggerated hip and knee flexion
  - Inability to dorsiflex ankle or great toe from push-off through swing phase
  - Compensation to allow toes to clear during swing phase
- Hindfoot inversion
  - Patient walks on lateral border of foot.
- Inability to dorsiflex ankle
  - May check by asking patient to walk on heels
  - Manual muscle testing with patient seated on examining table with knee flexed
- Lack of eversion
  - Varus hindfoot
  - Over time, may become a fixed inversion contracture
- In some disease processes (eg, Charcot-Marie-Tooth disease) toe dorsiflexion is spared, creating claw toe deformities.
  - Patient attempts to compensate for lack of ankle dorsiflexion with toe extensors, worsening claw toe deformities.
  - Even when toe extensors are involved in the palsy, flexor tendons may become contracted.
  - Passive dorsiflexion of the ankle will reveal this.
  - With equinocavovarus foot contracture, calluses may form under metatarsal heads, particularly the fifth.
  - Sensation may be diminished on the dorsal and lateral aspects of the foot.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Imaging is typically unnecessary for patients with foot drop except in the following situations:
  - Consideration should be given to MRI:
    - If there is concern for mass effect creating a compressive neuropathy: lumbar spine, common peroneal nerve at fibular head
    - To rule out tibialis anterior tendon rupture (should be evident on clinical examination alone)
  - Consideration should be given to radiographs of foot or ankle:
    - To rule out stress fracture
    - To better define bony deformity (fixed deformity, associated ankle or foot arthritis; important because arthrodesis may need to be considered in lieu of or in combination with tendon transfer)
- Electrodiagnostic studies
  - Absence of recovery at 1 year and particularly at 18 months is highly suggestive that recovery of nerve function will not occur.
  - Nerve conduction studies and electromyography
  - Baseline and follow-up studies to determine if any recovery evident
  - Important to determine if tendon transfer is warranted
  - Tendon transfer should not be performed if nerve function may recover!
  - Absence of recovery at 1 year and particularly at 18 months is highly suggestive of no recovery.
  - We recommend consultation with a neurologist to confirm interpretation of electrodiagnostic studies.
  - Studies may also define function of PTT.
    - Important when considering dynamic PTT transfer versus PTT tenodesis
    - A tendon transfer of a healthy tendon immediately reduces its strength on manual muscle testing from 5/5 to 4/5, so if it is already compromised, then the tendon transfer will do little more than create a tenodesis.
    - Useful in determining if a more proximal compressive neuropathy exists

**DIFFERENTIAL DIAGNOSIS**

- Tibialis anterior tendon rupture
- Cerebrovascular accident
- Lumbar spine radiculopathy
- Hereditary sensorimotor neuropathy
- Leprosy
- Poliomyelitis
- Cerebral palsy (spastic)

**NONOPERATIVE MANAGEMENT**

**Bracing with an ankle–foot orthosis (AFO)**

- Requires a fixed AFO in flaccid paralysis
- May be a flexible AFO with common peroneal palsy
    - Requires plantarflexion stop
- Equinus contracture may need to be corrected to facilitate brace wear.
  - Achilles stretching
  - Botulinum toxin injection
  - Tendo Achilles lengthening (TAL)
- Varus deformity
  - If flexible may be corrected with bracing
  - If fixed, bracing is difficult.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- The surgeon must confirm that motor function will not recover before proceeding with tendon transfer.
  - Serial clinical examination
  - Serial electrodiagnostic studies (at least one compared to baseline)
- The surgeon must determine what motor function persists:
  - Tibial nerve
  - PTT (inversion)
  - Gastrocnemius–soleus (plantarflexion)
  - None (flaccid paralysis)
- The surgeon must evaluate for equinus contracture.
  - The surgeon should be prepared to perform TAL if necessary (see Tech Fig 1A–D).
- Flexible versus fixed deformities
  - Flexible deformity typically corrects with tendon transfer alone.
  - Fixed deformity
    - May require capsular release or even arthrodesis
- Toe contractures
  - Although claw toe deformity may not be evident with the ankle plantarflexed, once the deformity is corrected, toe contractures may become obvious.
  - Dorsiflexing the ankle will put the contracted flexor hallucis and digitorum on stretch, thereby revealing the toe contractures.
  - The surgeon should be prepared to address toe contractures as part of the procedure.
- Tendon transfer anchoring
  - We routinely use interference screws to anchor tendon transfers to bone.
  - Need to have an anchoring system available
  - Alternatively, anchoring to existing distal tendon or existing soft tissues in the foot may be possible.
  - In our experience, anesthesia should maintain complete muscle relaxation and paralysis during the procedure; otherwise, the success of the tendon transfer may be compromised.
At the conclusion of the procedure we often perform botulinum toxin injections into the gastrocnemius–soleus complex to further protect the tendon transfer postoperatively.

**Positioning**

- **Supine**
- If the PTT will be transferred through the IOM or if a peroneal tendon will be used for correction of flaccid paralysis, we routinely place a bolster under the ipsilateral hip to afford optimal lateral exposure. Once the lateral tendon is harvested or the PTT transferred through the IOM, the bolster may be removed.
- We routinely use a thigh tourniquet.

**Approach**

- Multiple relatively small incisions are needed; extensile exposures are unnecessary.

---

**ACHILLES LENGTHENING**

**Indications**

- Not always necessary, but typically required when foot drop occurs
- Without active dorsiflexion the gastrocnemius–soleus’ antagonist is lost, often leading to an Achilles contracture.
- Occasionally patients maintain an active stretching program, thereby avoiding an Achilles contracture.
- Weakening of the gastrocnemius–soleus complex may be beneficial since a transfer of a healthy muscle–tendon unit is subject to an automatic one-grade loss of power (5/5 manual muscle testing drops to 4/5 with transfer).
- Occasionally we use botulinum toxin in the gastrocnemius–soleus complex when performing a PTT transfer for foot drop.

**Technique**

- Determined by the Silfverskiold test
- Equinus contracture with the knee in extension and flexion *(TECH FIG 1A)*

---

**TECH FIG 1** • Tendo Achilles lengthening. **A.** Equinus with knee in flexion and extension suggests tight gastrocnemius and soleus. **B.** Initial Achilles hemisection. **C.** Second Achilles hemisection (opposite direction from first), to be followed by third and final hemisection in same direction as first. **D.** Dorsiflexion re-established after Achilles lengthening.
Triple hemisection (Hoke procedure) because both the gastrocnemius and soleus are contracted (TECH FIG 1B–D).
- Equinus contracture only with the knee in extension: gastrocnemius–soleus recession (Strayer procedure) because only the gastrocnemius is contracted.

**Posterior Tibial Tendon Transfer Through the Interosseous Membrane**

- **Advantages**
  - PTT in direct line from its muscle through the IOM to the lateral cuneiform (our preferred site for tendon anchoring)
  - Anchor point slightly lateral of midline to promote dorsiflexion and eversion
- **Disadvantage**
  - PTT may be constricted and stenosed within narrow window created in distal IOM.

**Posterior Tibial Tendon Harvest**

- Make a 4-cm longitudinal incision over the medial navicular and PTT on the medial foot.
- Open the PTT sheath to expose the tendon.
- Release the PTT insertion on the medial navicular.
- Alternatively, use a chisel to elevate some medial navicular bone with the PTT release from the medial navicular (may allow for another centimeter of tendon for transfer) (TECH FIG 2A).
- Isolate the PTT attachment on the medial navicular and the tendon fibers that begin to course to the plantar midfoot (TECH FIG 2B).
- With the PTT fibers isolated, transect them to release the PTT distally.
  - Be sure to fully isolate the PTT fibers; the medial plantar nerve and the plantar medial complex of veins is in close proximity.
  - Accidentally transecting the nerve leads to loss of sensation in the plantar medial forefoot.
  - Violating the veins may make it difficult to achieve satisfactory hemostasis as these veins may then retract under the foot.
- Thin the distal stump of the PTT to facilitate its transfer into an osseous tunnel that will be created in the foot (TECH FIG 2C).

**TECH FIG 2 • Posterior tibial tendon (PTT) harvest**

A. Elevating PTT with a sliver of medial navicular may allow longer tendon harvest. B. Isolating PTT. C. Distal PTT needs to be trimmed to allow it to pass into dorsal foot osseous tunnel. D, E. Tag suture in distal PTT. F. Transfer of PTT to proximal medial wound. A 3-cm incision is made over PTT musculotendinous junction. (continued)
■ Place tag sutures in the distal PTT (TECH FIG 2D,E).
■ Make a more proximal medial incision at the PTT musculotendinous junction on the posterior tibia.
  ▪ 3-cm incision (TECH FIG 2F)
    ▪ Flexor digitorum tendon is usually encountered first.
    ▪ Deep to the FDL, directly on the posteromedial tibia, the PTT is identified.
    ▪ Place a blunt retractor around the PTT through this more proximal wound to isolate it.
■ Mobilize the distal PTT.
    ▪ Alternate tension on the proximal tendon through the proximal wound and the distal tag sutures (TECH FIG 2G), then apply tension proximally only.
    ▪ This may not work.
    ▪ The medial incision may need to be extended proximally to allow access to the posterior medial malleolus, a common location where the tendon may bind.
    ▪ Once mobilized, the distal aspect of the PTT may be transferred to the proximal wound (TECH FIG 2H).
■ Tendon will desiccate rapidly, so we keep it tucked in the proximal medial wound.

### Posterior Tibial Tendon Transfer Through the Interosseous Membrane
■ Lateral incision on anterior aspect of distal fibula, at distal tibiofibular syndesmosis
■ Careful exposure of anterior IOM
■ Elevate the anterior compartment soft tissues.
■ A branch of the peroneal artery courses on the anterior IOM and is at risk.
■ Create a generous window in the distal IOM (TECH FIG 3A).
■ From tibia to fibula
■ About 3 to 4 cm long
■ Pass a tonsil clamp through the IOM directly on the posterior aspect of the tibia to exit in the proximal medial wound (TECH FIG 3B).
■ The posterior neurovascular structures (tibial nerve and posterior tibial artery) are at risk, so be sure the clamp is directly on the posterior tibia.
Use the tonsil clamp to grasp the tag sutures of the PTT (TECH FIG 3C).
- Pull the tag sutures and PTT from the medial wound to the lateral wound, keeping the tendon directly on the posterior aspect of the tibia (TECH FIG 3D,E).
- Be sure that the window in the IOM does not impinge on the transferred tendon.
  - If there is stenosis, then further enlarge the window so that the tendon easily glides between the tibia and fibula.
- Keep the tendon end in the wound to limit desiccation.

**Preparation of the Dorsal Foot Anchor Site**

- Fluoroscopically identify the center of the lateral cuneiform.
  - Oblique foot views usually best define the lateral cuneiform (TECH FIG 4A).
- Center a 3- to 4-cm longitudinal skin incision directly over the lateral cuneiform.
- Dissect to the lateral cuneiform.
  - Protect the superficial peroneal nerve and extensor tendons.
  - Deep neurovascular bundle is usually medial to this approach.
- Expose and define the cuneiform.
  - We routinely use small-gauge hypodermic needles or Kirschner wires to mark the joints surrounding the lateral cuneiform and fluoroscopically confirm that the lateral cuneiform is defined by these markers (TECH FIG 4B).
  - Periosteum and capsular tissue are left intact.
  - Create an osseous tunnel in the center of the lateral cuneiform.
  - We routinely predrill the center with a Kirschner wire and confirm the starting point and trajectory of the wire fluoroscopically.
  - Remove the wire and introduce sequentially larger drill bits to enlarge the tunnel (TECH FIG 4C).

**TECH FIG 4** • Preparing dorsal foot osseous tunnel. A. Lateral cuneiform is identified fluoroscopically. B. Borders of lateral cuneiform are exposed and marked. C. Drill hole is created in lateral cuneiform and proper position is confirmed fluoroscopically. D. Osseous tunnel is gradually enlarged, first with drill bits, then dedicated reamer system for interference screw. E. Prepared osseous tunnel in lateral cuneiform.
Posterior Tibial Tendon Transfer to Dorsum of Foot

- Transferring the PTT deep to the extensor retinaculum with the extensor tendons diminishes the power of the transfer (which is by definition already weakened by one grade with transfer).
- Create a subcutaneous soft tissue tunnel from the dorsal foot incision to the more proximal and lateral lower leg incision using a curved Kelly or tonsil clamp (TECH FIG 5A).

Use the clamp to grasp the tag sutures and pull the tendon through the subcutaneous tunnel to the dorsal foot incision (TECH FIG 5B).

Before anchoring the tendon in the osseous tunnel, pull the tendon via the tag sutures into the tunnel to be sure that the tunnel diameter is appropriate.
- Pass a Beath pin or drill bit (has an eye to place suture) through the tunnel and the plantar skin (TECH FIG 5C).
  - Because of the midfoot arch and the drill hole centered in the lateral cuneiform foot this pin or the drill bit will exit in the medial arch (TECH FIG 5D).
- Dorsiflex the ankle.
- With the tag sutures secured, pull the pin or drill bit through the plantar skin, thereby pulling the distal tendon end into the tunnel (TECH FIG 5E).
  - If the tunnel does not accommodate the tendon, then the tendon and tag sutures must be withdrawn and the tunnel enlarged.
  - Because of the angle at which the tendon enters the tunnel, we often need to guide the tendon into the tunnel with a forceps.
- Anchoring the tendon to bone
  - Some degree of stretching or accommodation is anticipated, so we routinely anchor the tendon with the ankle maintained in 10 degrees of dorsi-
### TECH FIG 5 (continued)

**G.** Tension applied on plantar tag sutures.
**H.** Augmenting anchoring. Suture anchor being placed within osseous tunnel.
**I.** Two anchors secured in tunnel (note separate tag suture of PTT).
**J.** Final fixation of tendon transfer in dorsal foot. Tendon fully tensioned with ankle dorsiflexed.

- **K, L.** Securing tendon to anchors and adjacent periosteum.
- **M.** Interference screw positioned.
- **N.** Screw advanced.
- **O.** Screw fully seated.

Have the assistant maintain full ankle dorsiflexion and tension on the tag sutures on the plantar foot.
We usually cut the tag sutures so they retract beneath the skin.
Rarely, we have used a well-padded button on the plantar foot to further augment the tendon’s anchor point. We do not routinely do so because of the risk for plantar skin necrosis from the button despite adequate padding.
In select patients, the dorsiflexed ankle will unmask claw toes due to flexor hallucis longus and flexor digitorum longus contractures. Consider flexor hallucis longus and flexor digitorum longus lengthenings, posterior to the ankle and tibia via the more proximal medial approach, or percutaneous tenotomies at the plantar toes.

- A properly sized isolated interference screw is probably adequate.
- However, we typically augment the anchor point with several nonabsorbable sutures from the periosteum surrounding the tunnel to the tendon directly at the entrance to the tunnel.
- To further augment the anchor point: before advancing the tendon and tag suture into the tunnel, place one or two suture anchors within the tunnel. Then advance the tendon into the tunnel and secure the tendon with the anchors. By tightening these sutures, the tendon may be pulled even further into the tunnel. An interference screw and periosteal sutures may still be used.
POSTERIOR TIBIAL TENDON TRANSFER ANTERIOR TO THE TIBIA

Advantages
- PTT has no opportunity to stenose in the IOM.
- Glides smoothly around anteromedial tibia
- Anchor point slightly lateral of midline to promote dorsiflexion and eversion

Disadvantage
- PTT is not in direct line from its origin to anchor point in the foot; it must travel around medial tibia.
- Anchor point is in the middle (second) cuneiform.
- Central location so it cannot provide an eversion moment
- However, typically unimportant since with PTT transfer the agonist–antagonist balance between PTT and peroneus brevis is again re-established by being neutralized.

Achilles Lengthening
- Same as for PTT transfer through IOM described earlier (TECH FIG 6)

Posterior Tibial Tendon Harvest
- Same as for PTT transfer through IOM described earlier (TECH FIG 7)

Preparation of the Dorsal Foot Anchor Site
- Similar to preparation of dorsal foot anchor site described earlier for PTT transfer through IOM

TECH FIG 6 • Adequate dorsiflexion (essential for successful tendon transfer to re-establish dorsiflexion).

TECH FIG 7 • Approach to posterior tibial tendon (PTT) harvest. A. The two planned medial incisions. B. Planned dorsal foot incision. C–E. Harvesting PTT. C. PTT is isolated. D. Distal tendon is trimmed (contoured). E. Tag suture in distal end of tendon. (continued)
However, when transferring the PTT through the IOM we typically anchor the tendon to the lateral (third) cuneiform.

In contrast, when we transfer the PTT anterior to the medial tibia, we typically anchor the tendon in the middle (second) cuneiform.

Middle cuneiform is smaller than the lateral cuneiform.

In our experience, greater risk of fracture with drill hole, tendon transfer, and interference screw

Fluoroscopically identify the center of the middle cuneiform.

AP and sometimes oblique foot views best define the middle cuneiform.

Center a 3- to 4-cm longitudinal skin incision directly over the middle cuneiform.

Dissect to the middle cuneiform.

Protect the superficial peroneal nerve and extensor tendons (TECH FIG 8A).

Protect the deep neurovascular bundle, usually encountered in this approach; it is directly deep to the muscle of the extensor hallucis brevis.

Expose and define the cuneiform.

We routinely use small-gauge hypodermic needles or Kirschner wires to mark the joints surrounding the medial cuneiform and fluoroscopically confirm that the medial cuneiform is defined by these markers (TECH FIG 8B).

Leave the periosteum and capsular tissue intact.

Create an osseous tunnel in the center of the medial cuneiform.

We routinely predrill the center with a Kirschner wire and confirm the starting point and trajectory of the wire fluoroscopically.

Remove the wire and introduce sequentially larger drill bits to enlarge the tunnel (TECH FIG 8C).

We use drill bits to a diameter of 4.5 mm.

With fluoroscopic confirmation, slight adjustments may be made with each successive drill bit to center the tunnel optimally in the cuneiform.

TECH FIG 7 • (continued) PTT is mobilized. F. PTT is identified at its musculotendinous junction. G. PTT is mobilized to allow transfer to proximal wound. H, I. Transferring PTT to proximal medial wound. H. Tendon is pulled into proximal wound. I. Proposed course for transfer to dorsum of foot.

TECH FIG 8 • Preparation of dorsal foot osseous tunnel. A. Dorsal incision over middle cuneiform. B. Middle cuneiform is identified and marked. (continued)
Use the reamer from the interference screw system to enlarge the tunnel to the desired diameter (TECH FIG 8D).

Typically, we enlarge the tunnel to 5.5 to 6.0 mm in the medial cuneiform.

**Posterior Tibial Tendon Transfer to Dorsum of Foot**

- Transferring the PTT deep to the extensor retinaculum with the extensor tendons diminishes the power of the transfer (which is by definition already weakened by one grade with transfer).
- Create a subcutaneous soft tissue tunnel from the dorsal foot incision to the more proximal and medial lower leg incision using a curved Kelly or tonsil clamp (TECH FIG 9A,B).

Use the clamp to grasp the tag sutures and pull the tendon through the subcutaneous tunnel to the dorsal foot incision.

Before anchoring the tendon in the osseous tunnel, pull the tendon via the tag sutures into the tunnel to be sure that the tunnel diameter is appropriate.

Pass a Beath pin or drill bit (has an eye to place suture) through the tunnel and the plantar skin (TECH FIG 9C,D). Because of the midfoot arch, this pin or drill bit will exit in the medial arch (TECH FIG 9E).

Dorsiflex the ankle.

With the tag sutures secured, pull the pin or drill bit through the plantar skin, thereby pulling the distal tendon end into the tunnel (TECH FIG 9F).

If the tunnel does not accommodate the tendon, then the tendon and tag sutures must be withdrawn and the tunnel enlarged.
Because of the angle at which the tendon enters the tunnel, we often need to guide the tendon into the tunnel with a forceps.

- Anchoring the tendon to bone
- Some degree of stretching or accommodation is anticipated in the posterior tibial muscle and tendon, so we routinely anchor the tendon with the ankle maintained in 10 degrees of dorsiflexion.
- A properly sized isolated interference screw is probably adequate.
- However, we typically augment the anchor point with several nonabsorbable sutures from the periosteum surrounding the tunnel to the tendon directly at the entrance to the tunnel.
- To further augment the anchor point
  - Before advancing the tendon and tag suture into the tunnel, place one or two suture anchors within the tunnel (TECH FIG 9G).

- Then advance the tendon into the tunnel and secure the tendon with the anchors. By tightening these sutures, the tendon may be pulled even further into the tunnel. An interference screw and periosteal sutures may still be used (TECH FIG 9H).
- Have the assistant maintain full ankle dorsiflexion and tension on the tag sutures on the plantar foot.
- We usually cut the tag sutures so they retract beneath the skin.
- Rarely, we have used a well-padded button on the plantar foot to further augment the tendon’s anchor point (TECH FIG 9I). We do not routinely do so because of the risk for plantar skin necrosis from the button despite adequate padding.
**BRIDLE PROCEDURE**

- **Advantages**
  - The "bridle" creates a balance to the foot and ankle.
  - Potentially can make the patient with flaccid paralysis brace-free

- **Disadvantage**
  - With flaccid paralysis, the tendon transfer is static, not dynamic.
  - Functions as a tenodesis
    - If procedure is successful, foot and ankle remain in neutral position at all times.

**Achilles Lengthening**

- Same as for PTT transfer through IOM described earlier

**Posterior Tibial Tendon Harvest**

- Same as for PTT transfer through IOM described earlier (TECH FIG 10)

**Harvest of the Peroneus Longus**

- With an adequate skin bridge from the anterior ankle distal tibial incision, make a 2- to 3-cm incision immediately posterior to the fibula, about 8 cm proximal to the tip of the fibula at the level of the peroneus longus' musculotendinous junction (TECH FIG 11A).
  - Protect the superficial peroneal nerve. However, with common peroneal nerve palsy, an injury to this terminal sensory branch will probably be inconsequential.
  - Sharply divide the peroneal retinaculum 2 to 3 cm longitudinally over the musculotendinous junction of the peroneus longus.
  - Divide the peroneus longus tendon at its musculotendinous junction (TECH FIG 11B).
  - Place a tag suture in the transected distal end of the tendon.
  - Make another 2- to 3-cm incision over the lateral cuboid (TECH FIG 11A).
  - Protect the sural nerve.
  - Isolate the peroneus longus tendon and pull its released proximal portion through this lateral foot wound (TECH FIG 11C,D).
  - Tuck the peroneus longus tendon in the distal lateral foot wound to keep it from desiccating.
  - The peroneus longus tendon will be passed to the anterior ankle wound (see below).

**TECH FIG 10** • Harvest of posterior tibial tendon for bridle procedure.

**TECH FIG 11** • A–C. Harvest of peroneus longus for bridle procedure. A, B. Two small incisions, the first at the musculotendinous junction of peroneus longus and the second where the tendon courses around the cuboid. C. Peroneus longus transferred to distal lateral incision. D. Anticipated course for peroneus longus in bridle procedure (note also approximate course of posterior tibial tendon transfer).
Posterior Tibial Tendon Transfer Through the Interosseous Membrane

- Make an incision over the lateral aspect of the distal anterior tibia.
- Carefully expose the anterior IOM (TECH FIG 12A).
- Protect the superficial peroneal nerve.
  - Divide the extensor retinaculum over the tibialis anterior and extensor hallucis longus tendons.
- Protect the deep neurovascular bundle (TECH FIG 12B).
- Protect the peroneal artery branch that courses on the anterior IOM.
- Create a generous window in the distal IOM (TECH FIG 12C).
  - From tibia to fibula
  - About 4 cm long
- Pass a curved Kelly or tonsil clamp through the IOM directly on the posterior aspect of the tibia to exit in the proximal medial wound (TECH FIG 12D).
  - The posterior neurovascular structures (tibial nerve and posterior tibial artery) are at risk, so be sure the clamp is directly on the posterior tibia.
- Use the tonsil clamp to grasp the tag sutures of the PTT.
- Pull the tag sutures and PTT from the medial wound to the lateral wound, keeping the tendon directly on the posterior aspect of the tibia (TECH FIG 12E).

- Be sure that the window in the IOM does not impinge on the transferred tendon. If there is stenosis, then further enlarge the window so that the tendon easily glides between the tibia and fibula.
- Keep the tendon end in the wound to limit desiccation.

Transfer of the Peroneus Longus

- Using a Kelly clamp, create a subcutaneous tunnel from the anterior distal tibial wound to the lateral foot wound (TECH FIG 13A).
- Spread this tissue carefully with the clamp to avoid any soft tissue impingement within the tunnel.
- Grasp the tag suture in the peroneus longus and pull the tendon from the lateral foot wound to the anterior distal tibial wound (TECH FIG 13B).

Transfer of Posterior Tibial Tendon Through the Tibialis Anterior Tendon

- Make a stab incision in the tibialis anterior tendon with proximal tension placed on the tibialis anterior tendon while the ankle is held in dorsiflexion.
- This will tension the distal extent of the tibialis anterior tendon before it is secured to the PTT.
- Avoid simply creating an incision in the tibialis anterior tendon in situ; this will render the tension in the medial aspect of the “bridle” ineffective.
Create an osseous tunnel in the middle cuneiform (TECH FIG 15A).

Create a subcutaneous soft tissue tunnel from the dorsal foot incision to the more proximal and anterior lower leg incision using a curved Kelly clamp.

Use the clamp to grasp the tag sutures and pull the tendon through the subcutaneous tunnel to the dorsal foot incision (TECH FIG 15B).

Before anchoring the tendon in the osseous tunnel, pull the tendon via the tag sutures into the tunnel to be sure that the tunnel diameter is appropriate.

Pass a Beath pin or drill bit (has an eye to place suture) through the tunnel and the plantar skin (TECH FIG 15C). Because of the midfoot arch, this pin or drill bit will exit in the medial arch (TECH FIG 15D).

Dorsiflex the ankle.

With the tag sutures secured, pull the pin or drill bit through the plantar skin, thereby pulling the distal tendon end into the tunnel (TECH FIG 15E).

### Preparation of the Dorsum of the Foot and Anchoring the Posterior Tibial Tendon

- Similar to that described for PTT transfer anterior to the tibia (see earlier)
- Transfer to the middle cuneiform
- A separate incision may be made (two limited incisions anteriorly) or the anterior distal tibial approach may be extended to the dorsum of the foot (single extensile anterior incision).

Pass the PTT through this stab incision in the tibialis anterior (TECH FIG 14).

If a more secure fixation between the tibialis anterior and PTT is desired, then consider a Pulvertaft weave.

While more weaving of the PTT through the tibialis anterior may afford greater fixation, it may in turn diminish the excursion of the PTT, thereby limiting the amount of distal PTT that will rest within the middle cuneiform’s osseous tunnel.

### TECH FIG 13 • Transferring peroneus longus tendon from distal lateral foot wound to anterior lower leg wound.

A. Subcutaneous tunnel to grasp free end of peroneus longus. B. Tendon transferred.

### TECH FIG 14 • Posterior tibial tendon is transferred through the tibialis anterior. Note the pretensioning of the tibialis anterior to optimize tension in the bridle.

### TECH FIG 15 • A. Creating the osseous tunnel in middle cuneiform. B–G. Transferring posterior tibial tendon (PTT) from anterior lower leg wound to dorsum of foot. B. Tendon passed through subcutaneous tunnel to dorsum of foot. C. Beath needle with tag sutures from PTT passed through osseous tunnel. (continued)
Chapter 126  TENDON TRANSFER FOR FOOT DROP

TECH FIG 16 • With the foot balanced, tibialis anterior and peroneus longus are secured to posterior tibial tendon transfer to create the bridle.

TECH FIG 15 • (continued) D. Tension on tag sutures on plantar foot. E. Tendon passed into middle cuneiform osseous tunnel. F. Positioning interference screw. G. Interference screw fully seated with appropriate PTT tension achieved.

- With the PTT properly tensioned in the second cuneiform’s osseous tunnel, the PTT is anchored in a manner similar to that described earlier for the other techniques (interference screw with or without suture anchor in tunnel) (TECH FIG 15F,G).

Securing and Tensioning Tibialis Anterior and Peroneus Longus to the Posterior Tibial Tendon

- Maintain the ankle in 10 degrees of dorsiflexion.
- Balance the foot with respect to varus or valgus; it should have a neutral to slight valgus heel.
- Tibialis anterior
  - Tension the tibialis anterior proximally and suture the tibialis anterior and PTT to one another at the point where the PTT passes through the tibialis anterior.
  - Reinforce this connection with several more side-to-side sutures between the two tendons, both proximal and distal to where the PTT passes through the tibialis anterior.
- Peroneus longus
  - Approximate the peroneus longus to the PTT where it passes anterior to the distal tibia and ankle, with maximum tension applied (TECH FIG 16).
  - Without support, the ankle should maintain dorsiflexed ankle and neutral hindfoot positions.
POSTOPERATIVE CARE

- We routinely place a well-padded short-leg cast in the operating room to protect the transfer, with the ankle in maximum dorsiflexion.
- At first follow-up (2 to 3 weeks), we remove the cast while maintaining ankle dorsiflexion.
- To protect the transfer, the ankle should not be allowed to plantarflex.
- A new short-leg cast is applied, one that allows touch-down weight bearing.
- Follow up at 5 to 6 weeks from surgery.
- The short-leg cast is removed, again protecting dorsiflexion.
- Wound inspection
  - Without allowing the ankle to plantarflex, the cast is removed.
  - Consideration may be given to creating a temporary AFO.
- We typically place the patient in a short-leg walking cast at this point, with the ankle in near-maximum dorsiflexion. The patient is encouraged to walk.
- At 8 to 10 weeks
  - The patient can typically discontinue use of the cast.
  - AFO for ambulation is typically worn until 4 to 5 months after surgery. During the final month of brace wear, the surgeon can consider hinging the AFO and placing a plantarflexion stop at neutral.
  - A cam boot is used for sleeping; it is typically worn until 4 to 5 months after surgery.
  - A physical therapy program is initiated to train the PTT to function as an ankle dorsiflexor.
- Return to brace-free full function is not recommended before 6 months.

OUTCOMES

- Select case series of PTT transfers for foot drop and bridle procedures suggest a satisfactory outcome in a majority of cases.

COMPLICATIONS

- Infection
- Wound dehiscence. The wound must be healed before initiating active dorsiflexion (usually not a problem because cast is maintained for at least 8 weeks).
- Failure of the tendon transfer anchoring point; less common with newer anchoring system
- Imbalance of bridle procedure: tibialis anterior and peroneus longus must be properly tensioned intraoperatively

GENERAL CONSIDERATIONS

Anterior Approach (Smith-Robinson)

- The approach chosen depends on a number of factors, including the spinal segments that must be exposed, the nature of the procedure to be performed, and the patient’s body habitus.
- In general, the Smith-Robinson approach allows access from C2 down to T1 in most patients. However, local variations in patient morphology may either limit or increase the extent of available exposure.
- Ease of access to the C2-3 disc depends on the location of the mandible and can be assessed on the preoperative lateral radiograph.
- Nasal intubation is preferable when approaching this level as it allows the mandible to be maximally closed, away from the line of sight of the disc.
  - Depending on the location of the mandible with respect to C3-4, nasal intubation may be preferable in certain instances of C3-4 access as well.
  - For pathology at C7-T1 or distal, careful scrutiny of the disc space with respect to the sternal notch on lateral radiographs will help to assess whether a sternal-splitting approach may be necessary.
  - In some patients with long necks, access to T2 or even T3 may be possible with a standard Smith-Robinson approach.
  - In those with short or stocky necks, even getting to C7 may be a challenge (Fig 1).
- Imaging studies should be evaluated for anatomic variations such as medial aberrancy of the vertebral artery.

- Considerable debate exists as to whether the “sidedness” of approach affects the rate of postoperative superior laryngeal nerve palsy. The literature is not conclusive but suggests higher rates with right-sided approaches.
  - If a patient has had prior neck surgery and it is desirable to approach the spine from the opposite side to avoid scar, a preoperative indirect laryngoscopy should be performed by ear, nose, and throat (ENT) consultation to rule out a recurrent laryngeal nerve palsy.
  - If one exists, the spine must be approached from the side of the injury to avoid the possibility of bilateral vocal cord palsy. If one does not exist, the spine can be approached from either side.

Lateral Retropharyngeal Approach (Whitesides)

- This approach can be used for anterior access to the upper cervical spine but not the basiocciput.
- It is often used for high cervical bony lesions, including tumors or infections for which a posterior approach is not possible, unstable fractures or dislocations with deficient or incompetent posterior elements, or posterior nonunions (particularly for fusions of C1 to C2).
- It is also useful for access to high cervical ventral or ventrolateral intradural lesions such as neurofibromas or meningiomas.
- It allows unilateral access to C1 to C3. Access to the far contralateral side requires a second approach.
- Potential complications include injury to the spinal accessory nerve and the vertebral artery. The jugular vein also lies within the operative field and can be a site of significant bleeding if inadvertently injured.
- Significant retropharyngeal swelling has occurred and can result in prolongation of intubation if the patient’s airway becomes obstructed.

Anterior Approach to the Cervicothoracic Junction (Transmanubrial-Transclavicular Approach)

- There are several different approaches for exposing the cervicothoracic junction, including the transmanubrial-transclavicular and the sternal-splitting (median sternotomy) approaches.
  - The sternal-splitting (median sternotomy) approach may be useful in providing improved distal access to the upper thoracic spine.
  - Deep dissection is essentially the same for the two approaches.
  - Cranial to caudal dissection is recommended to avoid injury to the major crossing vessels distally (eg, the left brachiophical vein).
  - With a left-sided approach, the thoracic duct is at greater risk. It passes into the left venous angle between the subclavian artery and the common carotid artery.
With a right-sided approach, the recurrent laryngeal nerve is at greater risk because of its greater variability versus the left side, where the nerve is more constant in its location in the tracheoesophageal groove.

**POSITIONING**

**Anterior Approach (Smith-Robinson)**
- The patient is positioned supine with the neck slightly extended.
- The amount of extension tolerated by the patient without developing neurologic symptoms should be assessed preoperatively and not exceeded during positioning (FIG 2).
- A bump (eg, rolled sheets) under the shoulders facilitates gentle extension of the spine.
- A halter or Garner-Wells tong is optional but not routinely necessary for anterior cervical discectomy and fusion (ACDF) surgery.

A foam doughnut is placed behind the occiput to prevent pressure necrosis.
- The head is placed in neutral rotation. Doing so provides landmarks (the nose and the sternal notch) that are in line with the longitudinal axis of the spine for orientation during decompression and instrumentation.
- Depending on the relationship of the mandible to the upper cervical spine, proximal approaches to C2-3 may be easier if the head is gently rotated away from the side of the approach.
- The amount of rotation should be kept in mind to prevent disorientation during surgery.
- The shoulders are gently taped down to facilitate intraoperative radiographic visualization.
- Excessive force should be avoided when taping down the shoulders to avoid brachial plexus injuries.
- Spinal cord monitoring (eg, somatosensory evoked potentials [SSEP] and motor evoked potentials [MEP]) can be used to help prevent positioning-related nerve injuries, but it is not completely sensitive in detecting injury.

**Lateral Retropharyngeal Approach (Whitesides)**
- The patient is placed supine with the head turned away from the side from which the approach will be performed unless the patient is constrained in a halo for instability reasons.
  - If this is the case, the exposure will be more challenging but still possible.
  - Nasotracheal intubation opposite the side of the approach is desirable as it allows the jaw to be fully closed, offering the least inhibited exposure.
- The pinna (earlobe) can be retracted forward and sewn anteriorly to allow better access to the styloid process and posterior ear area.
- The entire cervical region and lower face is prepared and draped.

**ANTERIOR APPROACH (SMITH-ROBINSON)**

**Incision and Superficial Dissection**
- A transverse incision placed in a skin crease is more cosmetic and suffices for accessing up to three disc levels in most instances.
  - A longitudinal incision, although less cosmetic, allows for a more extensile approach (C2-thoracic spine) and should be considered when three or more discs require access, or if the patient has a very thick, muscular neck.
- The incision is made using palpable anterior structures as a guide (ie, C3 hyoid bone, C4-5 thyroid cartilage, C6 carotid tubercle, C7 cricoid cartilage) (TECH FIG 1A).
  - The preoperative lateral radiograph can also be used to determine roughly where to make the incision to allow optimal access to the desired disc(s).
  - The surgeon should try to make the incision such that it will be in line with the “line of sight” of the intended disc space (TECH FIG 1B).
  - Transverse incisions may extend from the anterior two thirds of the sternocleidomastoid (SCM) to beyond the midline.
- Longer incisions and greater tissue mobilization facilitate multilevel procedures and will heal with a nearly imperceptible scar if placed within a natural skin crease.
- Vertical incisions, if used, are placed along the medial border of the SCM.
- The incision is continued through the subcutaneous fat to the platysma (TECH FIG 1C).
- The platysma is divided in line with the skin incision using electrocautery.
- Blunt dissection with scissors undermines the edges of the platysma.
- This allows for greater mobilization of the soft tissues, which is helpful in accessing multiple disc levels and getting enough exposure to place plates and screws.
- Superficial veins crossing the field of dissection may need to be ligated to facilitate exposure (TECH FIG 1D).
Deep Dissection

- The anterior border of the SCM is identified.
- Blunt dissection is then carried through the deep cervical fascia directly medial to the SCM.
- The SCM is retracted laterally to allow palpation and identification of the carotid artery (TECH FIG 2A).
- The carotid artery should be visualized and will form the lateral border of the approach; the esophagus will define the medial border of the approach.

Once the carotid is identified, a plane through the pretracheal fascia lying between the carotid sheath and the medial structures (thyroid gland, trachea, and esophagus) is created (TECH FIG 2B).
- Finger dissection in this plane is useful in allowing extensible exposure.
Extending the Exposure

- If surgery involves one level, minimal mobilization may be necessary. If the surgery involves multiple levels or the skin incision is not collinear with the desired disc space, greater mobilization is helpful.
- In general, crossing structures should be preserved if possible to avoid potential injury to neural structures (e.g., laryngeal nerves). Blunt dissection with scissors, Kittners, or fingers works best.
  - The superior thyroid vessels typically overlie C3-4, and the inferior thyroid vessels generally overlie C6-7.
  - The omohyoid is encountered crossing distal-lateral to cephalad-medial in the interval medial to the sternomastoid at roughly the C6 level. It can be divided with electrocautery or left intact.
  - Dividing the omohyoid will allow for a more extensile cephalad-caudal exposure and less tension on the wound for easier placement of plates and screws in multilevel or very distal constructs.

Elevation of Longus Colli and Identification of Levels

- Using bipolar electrocautery, subperiosteal elevation of the longus colli should be done to the level of the uncinate processes bilaterally, and at least from the midportion of the vertebral body above to the midportion of the body below the level for which discectomy is planned (TECH FIG 3A).
- Time and care spent on carefully elevating the longus colli facilitates proper, stable placement of self-retaining retractors, which in turn facilitates decompression and accurate placement of hardware.
- Retractor blades are then placed beneath the elevated longus colli (TECH FIG 3B).
- Careful placement of retractors will help avoid injury to the esophagus and sympathetic chain (which runs along the ventral surface of the longus colli).
- TECHNIQUES FIGURE 3C represents a cross-sectional view at the C5 level demonstrating the plane of dissection for the Smith-Robinson approach.
- Location of the appropriate level should be ensured by intraoperative radiographs before disruption of the disc.
**Chapter 1**

**ANTERIOR CERVICAL APPROACHES**

---

**Incision and Superficial Dissection**

- A transverse incision is extended from the mastoid tip, posterior to the ear, and is carried along the inferior border of the mandible, preferably in a natural skin crease.
- The incision is then directed caudally along the anterior border of the SCM (TECH FIG 4A).
- This incision can be extended as needed according to the amount of distal cervical spine exposure required. It can be carried as far as the sternal notch.

---

**LATERAL RETROPHARYNGEAL APPROACH (WHITESIDES)**

**Incision and Superficial Dissection**

- The incision is then carried through the subcutaneous tissues and platysma muscle using electrocautery.
- Dissection is carried out using blunt dissection techniques in the subplatysmal plane, allowing the creation of superior-anterior and inferior-posterior musculocutaneous flaps (TECH FIG 4B).
- The superior-anterior flap is elevated to the inferior border of the parotid gland.
- The greater auricular nerve is identified and dissected out of the subcutaneous tissue both caudally

---

**TECH FIG 3** (continued) B. Self-retaining retractors can be placed beneath the elevated longus colli to allow an unimpeded view of the anterior spine. Care should be taken to avoid injuring the esophagus and sympathetic chain during placement of the retractors. The use of cephalad/caudal retractors is optimal but not necessary in most cases. C. A cross-sectional view through the neck at C5 demonstrating the plane of dissection.

**TECH FIG 4** A. A transverse incision is extended from the mastoid tip and is carried along the inferior border of the mandible, turning caudally and continuing along the anterior border of the sternocleidomastoid muscle. B. The incision is carried through the subcutaneous tissues and platysma muscle using electrocautery in line with the incision. Subplatysmal flaps are developed with blunt dissection techniques to allow adequate mobilization of tissue. (continued)
C. The greater auricular nerve is identified and mobilized from the subcutaneous tissues to allow adequate retraction. It is sometimes necessary to sacrifice the greater auricular nerve. This will result in a small area of insensate skin but otherwise has no functional significance. D. The external jugular vein and collaterals are mobilized or ligated as needed. The sternocleidomastoid is mobilized anteriorly with the carotid sheath. For additional exposure the sternocleidomastoid can be taken down from the mastoid prominence through the tendinous insertion.

- It is occasionally necessary to sacrifice the greater auricular nerve; this will leave the patient with a small insensate patch of skin but no long-term functional deficit.
- The external jugular vein is identified and then mobilized or ligated as needed.
- The SCM is mobilized and retracted medially and anteriorly with the carotid sheath.

**Mobilization of Sternocleidomastoid**

- Depending on the amount of exposure required, the SCM may be detached partially or entirely from its tendinous insertion at the mastoid prominence.
  - Be sure to leave enough tissue cuff to allow reapproximation of the muscle on closure.
- Take care to identify and protect the spinal accessory nerve, which enters the SCM about 3 cm distal to the tip of the mastoid process.
  - For limited exposure, the spinal accessory nerve can be retracted anteromedially with the SCM (TECH FIG 5).
  - For more extensive exposure, it can be dissected off the jugular foramen in a cephalad direction and retracted posterolaterally while the SCM is everted.

**Deep Dissection**

- Lymph nodes found in the field of dissection and around the spinal accessory nerve can be excised.
- The lateral process of C1 is now easily palpable about 1 cm distal to the mastoid process.
- The interval between the jugular vein and the longus capitis muscles is then created, allowing access to the retropharyngeal space.
- The retropharyngeal space can be opened further with blunt dissection techniques employing scissors, Kittners, or fingers.
- A sharp elevator or bipolar electrocautery can then be used to elevate the longus capitis and longus colli muscles from the transverse processes and lateral masses of C1 and C2 (TECH FIG 6A).
- Retraction is best accomplished by bending a malleable retractor so that it can be used as a lever against the contralateral transverse process, thus elevating the soft tissues anteriorly and medially (TECH FIG 6B).

**TECH FIG 4 (continued)**

- External jugular vein
- Parotid gland
- Great auricular nerve
- Sternocleidomastoid

**TECH FIG 5**

- The spinal accessory nerve is identified as it enters the sternocleidomastoid about 3 cm distal to the tip of the mastoid process and retracted anteriorly with the sternocleidomastoid. The lateral process of C1 will lie essentially in the middle of the field of dissection, about 1 cm distal to the mastoid process.
Bipolar electrocautery can be used to elevate the longus capitis and longus colli muscles subperiosteally from the transverse processes and lateral masses of C1 and C2. Plane of dissection for the retropharyngeal approach. For deep retraction, a malleable retractor can be used as a lever against the contralateral transverse process, allowing elevation of the soft tissues anteriorly and medially.

ANTERIOR APPROACH TO THE CERVICOTHORACIC JUNCTION (TRANSMANUBRIAL-TRANSCLAVICULAR APPROACH)

Incision and Superficial Dissection
- A standard Smith-Robinson approach is taken, with the incision extended distally over the manubrium (TECH FIG 7A).
- The sternal and clavicular heads of the SCM are released at the tendinous attachments and retracted proximally and laterally. Be sure to leave enough tissue cuff to allow reapproximation of the muscle on closure.
- Likewise, the sternohyoid and sternothyroid are sectioned and retracted proximally and medially (TECH FIG 7B).
- The omohyoid is also generally sectioned for better exposure. It does not need to be repaired.

Mobilization of Clavicle
- The medial third of the clavicle and the left side of the manubrium is then cleared of any remaining soft tissue.
- The clavicle is then divided (typically with a Gigli saw) at the junction of the medial and middle thirds (TECH FIG 8A).
- Care must be taken to avoid injuring the left subclavian vein, which is normally closely apposed to the undersurface of the clavicle.
- At this point, the medial third of the clavicle can be disarticulated from the manubrium (TECH FIG 8B).
- If more exposure is needed, the left side of the manubrium can be removed in a piecemeal fashion by a rongeur.
- Alternatively, the medial third of the clavicle and a section of the manubrium can be removed together by careful sectioning. This will allow plate or wire reconstruction of the clavicle and manubrium if desired.
- If the manubrium and medial third of the clavicle are removed in this manner, the sternal head of the SCM can be left in continuity with the manubrium and reflected en bloc (TECH FIG 8C).

Deep Dissection
- The inferior thyroid vein and artery are often encountered with deeper dissection and may need to be ligated for better exposure.
- Careful blunt dissection proceeds in the same interval as for the standard Smith-Robinson approach (ie, between the carotid sheath laterally and the trachea and esophagus medially).
- The recurrent laryngeal nerve is almost always found between the esophagus and trachea on the left side of the neck within this plane.
- Blunt retractors are then placed and the carotid sheath, left brachiocephalic artery, and innominate vein are retracted inferolaterally (TECH FIG 9A).
- Likewise, a blunt retractor is used to retract the trachea, esophagus, left recurrent laryngeal nerve, and right brachiocephalic vessels inferolaterally to the patient’s right.
- The prevertebral fascia is then identified and incised to expose the vertebral bodies. Once adequately dissected, the surgeon can visualize and access as far distally as T3 or T4.
- TECHNIQUES FIGURE 9B represents a cross-sectional view at the cervicothoracic junction demonstrating the plane of dissection for the transmanubrial-transclavicular approach.
- At the completion of the procedure, the clavicle is replaced and plated.
TECH FIG 7 • A. The incision for a low Smith-Robinson approach can be extended along the anterior border of the sternocleidomastoid to the midsagittal plane at roughly the sternal notch and then extended vertically to just beyond the manubrial–sternal junction. B. The sternal and clavicular heads of the sternocleidomastoid are released and reflected laterally while the sternohyoid and sternothyroid muscles are sectioned and reflected medially. The omohyoid is usually released during the exposure. It does not need to be repaired.

TECH FIG 8 • A. The clavicle is divided at the junction of the medial and middle thirds, taking care to avoid injuring the left subclavian vein, which is normally closely apposed to the undersurface of the clavicle. B. The medial third of the clavicle can be disarticulated from the manubrium at the manubrioclavicular joint. This will generally provide adequate exposure to the C7-T1 level. C. For additional exposure, the left side of the manubrium can be removed piecemeal using a rongeur. A second option involves careful sectioning of the manubrium, which will allow lateral reflection of both the manubrium and medial third of the clavicle without disarticulation of the manubrioclavicular joint.
TECH FIG 9 • A. Blunt retractors are used to carefully retract the carotid sheath, left brachiocephalic artery, and innominate vein inferolaterally, while the trachea, esophagus, left recurrent laryngeal nerve, and right brachiocephalic vessels are retracted inferomedially. B. Cross-sectional view through the cervicothoracic junction demonstrating the plane of dissection for the transmanubrial-transclavicular approach.
ANATOMY

Posterior Cervical Musculature
- The muscles covering the posterior aspect of the cervical spine are arranged in three layers (FIG 1).
- Superficial layer: The trapezius muscle originates from the superior nuchal line of the occiput, the ligamentum nuchae, and the spinous processes of the upper thoracic spine. It inserts into the spine of the scapula and the acromion.
- Intermediate layer: The splenius capitis arises from the lower half of the ligamentum nuchae and upper six thoracic vertebrae, inserting onto the mastoid process and the lateral half of the superficial nuchal line under the sternocleidomastoid.
- The deep layer consists of the semispinalis capitis, the semispinalis cervicis, the multifidus, and the rotators, arranged from superficial to deep layers respectively.
  - The semispinalis capitis arises from the transverse processes of the upper six thoracic vertebrae and the articular processes of the midcervical vertebrae and inserts onto the occiput between the superior and inferior nuchal lines.
  - The semispinalis cervicis arises from the transverse processes of the upper six thoracic vertebrae and inserts onto the spinous processes of C2 to C5.
  - The multifidus muscle lies deep to the semispinalis cervicis. It originates from the articular processes of the lower cervical vertebrae and inserts onto the spinous processes of the upper cervical vertebrae.
  - The rotators lie deep to the multifidus. They originate from the transverse process of one vertebral and ascend obliquely to insert on the spinous process of the vertebra one or two levels cranial to their origin.

Suboccipital Musculature
- The rectus capitis posterior minor originates from the posterior tubercle of the atlas and inserts onto the medial half of the inferior nuchal line.
- The rectus capitis posterior major originates from the spinous process of the axis and inserts onto the lateral half of the inferior nuchal line.
- The obliquus capitis superior originates from the transverse process of the atlas and inserts onto the occiput laterally between the superior and inferior nuchal lines.
- The obliquus capitis inferior muscle originates from the spinous process of the axis and inserts onto the transverse process of the atlas.
- The suboccipital triangle lies between the rectus capitis posterior major and the superior and the inferior obliquus.
- The greater occipital nerve is the medial branch of the posterior division of the second cervical nerve at the medial angle of the suboccipital triangle. It runs cephalad between the semispinalis capitis and the obliquus inferior, toward the occiput, where it pierces the semispinalis capitis and the trapezius. It is responsible for cutaneous innervation of the back of the scalp (FIG 2).

Osteoligamentous Anatomy
- The external occipital protuberance or inion is an easily palpable bony landmark in the midportion of the occiput. The superior nuchal line extends as a bony ridge on either side of this prominence. A small ridge or crest, called the median nuchal line, descends in the medial plane from the external occipital protuberance to the foramen magnum. The inferior nuchal line runs parallel to the superior nuchal line, midway between the inion and foramen magnum (FIG 3).
- The atlas does not have a spinous process but has a posterior tubercle marking the center of the posterior arch.
- The spinous process of the axis is tall, bifid, and broadest in the cervical spine.
- A broad sheet of thick fibrous tissue called the posterior atlanto-occipital membrane extends from the posterior border of the foramen magnum to the superior border of the posterior arch of the atlas.
- The posterioratlantoaxial membrane is a broad, thin membrane extending from the inferior border of the posterior arch of the atlas to the superior border of the lamina of the axis.
- The tectorial membrane is the cranial extension of the posterior longitudinal ligament, running posterior to the transverse ligament to attach onto the anterior border of the foramen magnum.
- The anterior atlantoaxial ligament is the continuation of the anterior longitudinal ligament, extending from the inferior border of the anterior arch of the atlas to the front of the body of the axis (FIG 4).
- The pars interarticularis or isthmus of C2 is the waist of the posterior arch of C2, connecting the superior and inferior articular processes. The medial margin of the pars interarticularis along the superior border of the C2 lamina is a guide to the medial margin of the C2 pedicle.
- The C1–2 facet joint is oriented largely in the axial plane, while the C2–3 and remaining subaxial cervical facet joints are coronally oriented 45 degrees to the plane of the spine.
- The spinous processes from C3 to C6 are small and bifid. The C7 spinous process tends to be straight and long and terminates in a single tubercle. It is usually the longest of the cervical spinous processes.
- The lateral mass of the cervical spine refers to the lateral column of each vertebral body that includes the superior and inferior articular processes and the transverse foramen on either side.
  - It offers a secure fixation anchor for screw insertion from C3 to C6, particularly when the spinous process and lamina are fractured or removed.
  - A faint longitudinal groove marks the separation between the laminae and lateral masses.
  - The exiting nerve root and posterior portion of the transverse process lie anterior to the lateral mass.
  - The anteroposterior depth of the lateral mass reduces gradually from C3 (about 8.9 mm) to C7 (about 6.4 mm).
Superficial layer
- Trapezius

Intermediate layer
- Splenius capitis

Deep layer
- Semispinalis capitis
- Rectus capitis posterior minor
- Rectus capitis posterior major
- Obliquus capitis inferior
- Semispinalis capitis

Superficial, intermediate, and deep layers of the posterior cervical musculature are shown on the left. The suboccipital muscles lie deep to these muscles and are shown on the right.

FIG 2 • Anatomy of the suboccipital triangle. The suboccipital triangle lies between the rectus capitis posterior major, the obliquus superior, and the obliquus inferior. The greater occipital nerve is seen crossing the suboccipital triangle along its medial angle. The posterior arch of the atlas with the vertebral artery is seen in the floor of the suboccipital triangle.
FIG 3 • A. Bony anatomy of the occiput with muscular insertions. Superior, inferior, and median nuchal lines are the prominent bony ridges on the posterior occipital surface. The major posterior cervical muscles and muscles of the suboccipital triangle insert on these bony ridges and on the posterior occipital surface between these ridges. B. Sagittal cross-section showing the ligamentous architecture of the proximal cervical spine. Anterior and posterior atlanto-occipital as well as atlantoaxial ligaments and the ligaments stabilizing the odontoid process are depicted: the apical ligament of the dens and the transverse ligament of the atlas.
The lateral mass of C7 is elongated superoinferiorly but is thinner in the anterior posterior plane than the other cervical vertebrae.
The pedicles of the cervical vertebrae are smaller than those in the lumbar spine. The dimensions are generally appropriate for pedicle screw insertion at C2 and C7.
Computed tomography should be obtained in all patients before screw fixation to verify pedicle width and morphology, particularly between C3 and C6.

**Nerve Root Anatomy**
- The dorsal and ventral nerve roots formed from the respective rootlets enter a common sleeve of the arachnoid and dura mater.
- The nerve root runs 45 degrees anterolaterally and 10 degrees inferiorly to enter the intervertebral foramen by passing over the top of the corresponding pedicle.
- The dorsal nerve root lies anterior to the superior articular process, positioned at the tip of the superior articular facet medially and then coursing inferiorly to lie on top of the pedicle laterally.
- The ventral root lies anteroinferiorly adjacent to the uncovertebral joint.
- The cervical nerve roots occupy the lower third of the intervertebral foramen, while the upper two thirds of the foramen is filled with fat.
- In the lateral part of the intervertebral foramen, the dorsal nerve root is enlarged to form the dorsal root ganglion, which lies between the vertebral artery and a groove on the anterolateral aspect of the superior articular process (Fig 4).
- The dorsal and the ventral nerve roots join distal to the dorsal root ganglion outside the intervertebral foramen to form the spinal nerve.

**Vertebral Artery**
- The vertebral artery is a branch of the first part of the subclavian artery, lying anterior to the transverse process of the seventh cervical vertebra at its origin.
- The vertebral artery courses medially and posteriorly through the subaxial cervical spine within the transverse foramina of the sixth through the first cervical vertebrae.
- It is at risk of injury where it lies unprotected between the transverse foramina and during anterior procedures lateral to the disc space, particularly at the upper cervical levels (FIG 5).
- Anatomic variations in the course of the vertebral artery are not infrequent. Following its origin off the subclavian artery, the vertebral artery typically enters the C6 transverse foramen. Bruneau et al reported entry into the C3, C4, C5, or C7 transverse foramina in 0.2%, 1.0%, 5.0%, and 0.8% of patients, respectively.
- A 2% incidence of tortuosity of the vertebral artery has been reported, leading to a potentially dangerous medial course of the vessel within the vertebral body.
- More cephalad, after emerging from the transverse foramen of C2, the artery lies lateral to the C1–2 facet joint before it enters the transverse foramen of the atlas.
- The artery exits the transverse foramen of the atlas and continues posteromedially in a groove on the superior surface of the posterior arch of the atlas.
- It enters the foramen magnum by piercing the atlanto-occipital membrane about 10 mm from the midline.
- In approaches to the posterior cervical spine, the vertebral artery is at risk of injury during exposure of the posterior arch of the atlas and in the transverse foramina of C1 and C2 during screw insertion for occipitocervical or atlantoaxial fusion procedures.
- To protect the vertebral artery during these procedures, dissection should be limited to within 12 mm of the midline on the posterior aspect of C1 and within 8 mm of the midline on the superior surface of the posterior arch of the atlas.
- Further lateral dissection can be performed on the inferior surface of the C1 arch versus the superior surface because the vertebral artery runs on the superior surface of the C1 arch.
- The width of the lateral mass of the atlas averages 11.6 ± 1.4 mm. The height of the portion of the lateral mass of the atlas inferior to its posterior arch averages 4.1 ± 0.7 mm.
- The lateral mass of C1 thus can generally safely accommodate a 3.5-mm screw below its attachment to the posterior arch.
SURGICAL MANAGEMENT

Indications
- Posterior spinal cord decompression via laminoplasty or laminectomy
- Nerve root decompression via foraminotomy
- Occipitocervical or atlantoaxial decompression, fusion, and instrumentation
- Posterior cervical fusion
- Cervical pedicle or lateral mass instrumentation

Positioning
- The patient's cervical spine should be ranged in flexion and extension in the preoperative area to determine a safe range that does not produce symptoms. Movements of the neck during intubation should be minimized, particularly in myelopathic patients.
- Awake intubation and positioning should be considered in myelopathic patients with markedly reduced canal dimensions.
- In patients undergoing occipitocervical and atlantoaxial procedures, the chin should be tucked to facilitate exposure of the occipitocervical region. For subaxial procedures, slight flexion of the neck reduces overlap of the laminae and facet joints, making deep dissection easier and facilitating decompression of the central and lateral canal. The neck should be brought back into neutral position for fusion or instrumentation procedures.
- Hyperextended or hyperflexed positions under anesthesia, particularly when held for prolonged periods of time, may contribute to spinal cord injury.
- We recommend use of the Mayfield three-point clamp to hold the cranium during posterior occipitocervical and posterior cervical surgery. The clamp is secured to the operating table with an adaptor.
- We infrequently use intraoperative tong traction because we believe the amount of traction transmitted to the operative site is variable.
- The shoulders are pulled down and taped to the distal end of the bed to facilitate intraoperative radiographic visualization (FIG 6). Excessive traction on the shoulders should be avoided to minimize the risk of brachial plexus injury.
- The reverse Trendelenburg position reduces epidural venous congestion and intraoperative bleeding. We avoid the sitting position to minimize the risk of intraoperative air embolism.
- Bony prominences and peripheral nerves in the upper and lower extremities should be well padded to protect against intraoperative decubiti or neurapraxia.
- Allowing the abdomen to hang free facilitates venous return to the heart, maintains cardiac output, and decreases the required peak inspiratory pressure.
- Radiographs are obtained after positioning to verify cervical alignment. Placement of a radiopaque marker before obtaining these radiographs facilitates planning of the incision.

FIG 6 • Positioning of the patient for posterior cervical surgery. In the prone position, the patient's head is stabilized with a Mayfield three-point clamp while traction is applied through the shoulders by taping them down. The patient is in the reverse Trendelenburg position with the abdomen allowed to hang free.
POSTERIOR APPROACH TO SUBAXIAL SPINE

- A midline skin incision is used for most surgical procedures to the subaxial spine. Palpation of the prominent spinous processes of C2 and C7 beneath the skin or the use of intraoperative radiographs can help restrict the incision to the area that requires exposure.
- The incision is deepened through the relatively avascular median raphe, which is a condensation of the deep fascia. This appears as a “white line” in the midline.
- Electrocautery is then used to incise the ligamentum nuchae.
- Troublesome bleeding from the paraspinal muscles can be minimized by staying within the avascular median raphe.
- Intermittent palpation of the spinous processes helps the surgeon stay oriented to the midline. The posterior cervical paraspinal musculature generally originates laterally and caudally, passing obliquely cephalad.
- Reduction of intraoperative bleeding is facilitated by dissecting caudal to cephalad in a subperiosteal fashion.
- For laminoplasty or multilevel laminectomy, the interspinous tissues are cauterized to minimize bleeding and then stripped off the spinous processes.
- Deep retractors are inserted beneath the fascial layers directly on bone. Deep dissection is carried further laterally along the laminae.
- Localization of level is facilitated by identifying the large C2 and C7 spinous processes and the bifid spinous processes from C2 to C6.
- An intraoperative lateral radiograph should be obtained to confirm the operative levels.
- If facet fusion is not planned, the dissection should stop at the medial third of the facet joint and the facet joint capsule should be preserved.
- If facet fusion or instrumentation is required, the dissection is extended to the lateral border of the lateral mass.

POSTERIOR APPROACH TO OCCIPITOCERVICAL REGION

- The external occipital protuberance and the prominent bifid C2 spinous process can be palpated in most patients beneath the skin. A midline skin incision is made extending from just above the occipital protuberance to the cervical level required.
- The incision on the scalp is deepened down to bone, and the occiput is exposed in subperiosteal fashion from the inion down to the foramen magnum.
  - The dissection is carried laterally for a distance of 2.5 cm on either side of the median occipital crest. Excessive lateral dissection or retraction can injure the greater occipital nerve.
  - The incision is extended caudally through the ligamentum nuchae in the midline. Staying in the midline reduces blood loss.
  - Self-retaining retractors are applied at both ends of the incision.
  - The large bifid spinous process of C2 is easily identified. It is exposed subperiosteally by dissecting the attachments of the rectus capitis posterior major and obliquus capitis inferior from these structures.
  - The greater occipital nerve exits posteriorly along the inferior border of the obliquus capitis inferior muscle and can be preserved by keeping the dissection on the C2 posterior arch.
  - Preserving the soft tissue attachments to the distal and lateral aspects of C2 and the C2–facet joint helps maintain subaxial stability postoperatively.
  - The C1 ring lies deep in the space between the occiput and C2. The posterior arch of C1 has no muscular attachments.
- Soft tissue from the posterior arch of C1 is dissected subperiosteally, taking care to stay within 12 mm of the midline on the posterior aspect of the posterior ring of C1 and within 8 mm of the midline on the superior aspect of the posterior ring of C1 to avoid vertebral artery injury (TECH FIG 1).

TECH FIG 1 • The vertebral artery emerges from the transverse foramen of the atlas and courses medially in the groove on the superior surface of the posterior arch of the atlas. At the medial end of the groove it turns anteriorly and pierces the atlanto-occipital membrane about 10 mm from the midline.
EXPOSURE OF C1–2 FACET JOINT

- Exposure of the articulation between the lateral mass of C1 and the superior articular process of C2 is occasionally required for screw fixation of the lateral mass of C1 and fusion of this joint.
- After dissection and retraction of the muscles off the posterior aspects of C1 and C2 of the upper cervical spine, the lamina of C2 is identified.
- Soft tissue is carefully dissected off the lamina of C2 using a Freer elevator or dissector.
- Tracing the lamina of C2 proximally exposes the pars interarticularis of C2 and the superior medial corner of the C2 pedicle.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Condition</th>
<th>Pitfall</th>
</tr>
</thead>
<tbody>
<tr>
<td>Posterior vertebral arch fragments</td>
<td>Unstable or fractured fragments should be stabilized with a clamp during dissection to avoid inadvertent contusion of the spinal cord.</td>
</tr>
<tr>
<td>Stenotic canal</td>
<td>Excessive manipulation of the posterior elements in a patient with a stenotic canal should be avoided as it may inadvertently result in spinal cord injury.</td>
</tr>
<tr>
<td>Excessive bleeding</td>
<td>Venous bleeding from epidural veins can occasionally be profuse. The patient should be positioned in reverse Trendelenburg position to decrease the blood loss. Hemostatic agents and bipolar cautery are used to control bleeding from these veins.</td>
</tr>
<tr>
<td>Vertebral artery</td>
<td>The vertebral artery is endangered at lower cervical levels (C3 to C6) only if the transverse processes at these levels are destroyed by tumor or infection.</td>
</tr>
<tr>
<td>Spina bifida</td>
<td>Cervical spina bifida is a rare condition that can lead to cord damage during dissection if not recognized.</td>

</table>

EXPOSURE OF C1–2 FACET JOINT (continued)

- Exposure of the C1 lateral mass can be obtained by following the inferior arch of C1 laterally until the lateral border of the spinal canal is identified by visualizing its corresponding location on C2.
- From this point on C1, ventral dissection with a Penfield or Freer will allow palpation of the C1 lateral mass. The greater occipital nerve is encountered and swept distally. A large venous plexus is present and must be controlled with Gelfoam and bipolar cautery.

REFERENCES

DEFINITION
- The anterior approach can be used to access the thoracic spine for decompression, deformity correction, and stabilization. This approach allows for access to treat conditions such as intervertebral disc herniation, infection, tumor, and trauma.

ANATOMY
- The thoracic spinal cord may have a tenuous blood supply, particularly in patients with congenital anomalies and kyphosis.
- The midthoracic cord represents a watershed zone for vascularity. The artery of Adamkiewicz supplies the thoracic cord but can have a variable origin. Its origin is usually (80%) from the left side at the T10 level but can vary from T5 to L5.1

SURGICAL MANAGEMENT
Preoperative Planning
- Radiographs of the thoracic spine and chest should be obtained to determine the level of surgery and help in “rib counting.”
  - It is often helpful to obtain lumbar radiographs also to determine the number of lumbar segments below the most distal thoracic rib. Knowing this information preoperatively helps in counting “up” from the sacrum intraoperatively if needed.
  - In the absence of obvious bony pathology such as fractures, infections, or tumors, it is very easy to inadvertently localize the wrong level in the thoracic spine. The surgeon should be sure to have a strategy for intraoperative level identification based on careful scrutiny of radiographs and MRI or CT scans before surgery, understanding that the quality of portable films obtained intraoperatively may not be optimal.
  - When obtaining an MRI to better understand the nature of the pathology in relation to the thoracic spinal cord, the surgeon should ask for a topogram to be performed so that there is no question as to the level or levels of involvement.
  - On CT scan or MRI, the surgeon should pay close attention to the position of the aorta and inferior vena cava, especially on the axial cuts, as this may affect the side from which the spine is approached, especially if a corpectomy will be performed.
- Anesthesia considerations include the use of an oral gastric tube and double-lumen endotracheal tube, which allows for collapse of the ipsilateral lung.
  - If the surgical site is T10 or distal, selective deflation of the ipsilateral lung is usually not necessary.
  - If the surgical site is proximal to T10, selective deflation is helpful in keeping the lung out of the field, but it may lead to more postoperative issues with atelectasis.
- Neurologic monitoring is frequently used when performing thoracic operations.

Positioning
- The patient should be in the lateral decubitus position with the arms in prayer position.
- The thorax vertex should be positioned over the break of the bed, all pressure points should be padded, pillows should be placed between legs and arms, and an axillary roll should be used to prevent compression of the axillary vessels (FIG 1).
- The operating surgeon typically stands behind the patient during the exposure. However, it may be helpful to stand in front of the patient when performing the decompression, as the line of sight into the spinal canal is better from that vantage point.

Approach (Right Versus Left)
- Considerations for thoracic approaches include:
  - Approach from the side of herniation in cases of postero-lateral or lateral herniation.
  - Look at the axial CT or MRI scans to determine the location of the heart and great vessels. In most thoracic cases, these structures are either on the left or central. Thus, all other factors being equal, a right-sided approach is favored in most cases.
  - In the distal thoracic spine (eg, T10–12), the liver may be in the way of a right-sided approach. Because it is a bit more difficult to retract the liver than the kidney or spleen, a left-sided approach may be favorable.
- Considerations for thoracolumbar approaches include:
  - The left-sided approach is generally favored, as it is easier to mobilize the great arteries (aorta, iliacs) from their left-central position to the right, rather than mobilizing the great veins (which tend to be further to the right) toward the left.

FIG 1 • Patient placed in the lateral decubitus position. It is important to ensure that all bony prominences are well padded.
ANTERIOR THORACIC APPROACH FROM T1 TO T4

- For upper thoracic exposures a right-sided approach is preferred to avoid the heart.
- The surgeon makes a curved skin incision below the tip of the scapula (TECH FIG 1A).
- This incision is carried down to the latissimus dorsi muscle and then the latissimus is incised, leaving a cuff of the muscle on the scapula for later closure (TECH FIG 1B).
- A large retractor (ie, Richardson retractor) can then be held by the assistant while the surgeon incises the periosteum over the appropriate rib and then resects the rib as far anteriorly and posteriorly as possible (TECH FIG 1C).
- At this point, the chest is entered through the rib bed and a Finochietto or Omni retractor can be placed, with one of the blades holding the scapula up and out of the way.
- Now the lung can be deflated and retracted anteriorly and inferiorly (TECH FIG 1D).
- The pleura overlying the spine is now sharply incised. Placing suture into the edges of the pleura makes subsequent closure easier.
- Segmental vessels are identified and ligated as needed and the vertebral bodies (the "valleys") and disc spaces (the "hills") are identified.

TECH FIG 1 • Anterior thoracic approach from T1 to T4. A. A curved incision should be made just under the tip of the scapula. B. The incision is carried down to the latissimus dorsi. A cuff of muscle is left attached to the scapula for repair upon closure. C. The surgeon incises the periosteum over the rib. D. The deflated lung is retracted anteriorly and inferiorly while protecting the esophagus and great vessels.
ANTERIOR THORACIC APPROACH FROM T5 TO T12

- The surgeon should plan the incision directly over the desired rib (ie, 10th rib for T9-10 disc). A curvilinear skin incision is made along the path of the rib from the anterior border of the latissimus dorsi to the costochondral junction anteriorly (TECH FIG 2A).
- Due to the downslope of the ribs, it is generally preferable to make an incision that is more proximal rather than distal. If the incision is too distal, the ribs may impede access to the more proximal segment, necessitating a second thoracotomy. In contrast, it is easier to access levels that are distal to the rib that is resected. Thus, if in doubt as to the exact rib to be resected, the incision should be made more proximal.
- Skin and subcutaneous fat are incised to expose the trapezius and latissimus dorsi.
- The trapezius and latissimus dorsi are divided in line with the incision using electrocautery. The rhomboids may need to be split to gain more exposure cephalad.
- Once the correct rib is identified, the surgeon divides the periosteum over the upper border of the rib to avoid injury to the intercostal nerve and vessels (TECH FIG 2B).
- The rib is stripped subperiosteally anteriorly to the costochondral angle and as far posteriorly as possible (TECH FIG 2C).
- The rib is removed with a rib cutter and passed off the field. The rib is cut at the midaxillary line anteriorly and as far posteriorly as possible. The rib can be used as a strut graft or autologous bone graft.
- The periosteal rib sleeve and parietal pleura are incised to enter the thorax. A rib spreader is placed to hold the ribs apart (TECH FIG 2D).
- The ipsilateral lung is deflated and retracted medially to expose the parietal pleura overlying the spine.
- The parietal pleura overlying the spine is incised and retracted medially. Stitches can be placed in the parietal

TECH FIG 2 • Anterior thoracic approach from T5 to T12. (In these images, the patient’s head is to the upper left and the patient’s back is toward the surgeon.) A. The incision in planned directly over the rib. Injecting the subcutaneous tissues with a combination of anesthetic and epinephrine aids in hemostasis. B. The skin and subcutaneous tissues have been divided, exposing the desired rib. C. Subperiosteal exposure of the rib before excision. Note the thin parietal pleura beneath the rib bed. D. After excision of the rib the parietal pleura is entered, exposing the ipsilateral lung. (continued)
E. The parietal pleura and the underlying segmental vessels. F. The vertebral bodies and intervertebral discs are exposed after segmental arteries are ligated and the overlying soft tissues are removed. Once the costotransverse and costovertebral articulations are excised (G), the rib head can be removed with a high-speed burr (H).
pleura to make closure easier. The underlying segmental vessels are visualized (TECH FIG 2E).

- The segmental arteries arising from the aorta can run in an ascending, recurrent, horizontal, or descending direction depending on the level of involvement.
- The surgeon carefully ligates as few segmental vessels as possible to gain adequate exposure to the spine. Ligating more segmental vessels than necessary places the spinal cord at increased risk for ischemia because the thoracic spinal cord has a tenuous blood supply (TECH FIG 2F).
- In cases of suspected vascular anomalies, such as congenital kyphosis, the surgeon should consider temporary occlusion of the segmental vessels and check evoked potentials before vessel ligation. If a patient has had a prior spine exposure on one side, the surgeon should be wary of ligating the contralateral segmental vessels. Instead, the surgery should be performed through the previously exposed side, or a preoperative angiogram should be obtained to identify the important arterial feeders to the spinal cord.

- The intrathoracic vertebral bodies and intervertebral discs are now exposed. To gain access to the posterior intervertebral disc, the rib head may need to be removed.
- The costotransverse and costovertebral articulations are removed to excise the rib head (TECH FIG 2G).
- The soft tissues overlying the transverse process, pedicle, and vertebral body are removed.
- The superior edge of the pedicle is identified and followed back to the intervertebral space.
- The superior edge of pedicle is burred to expose the posterior intervertebral disc and lateral margin of the dura (TECH FIG 2H).

### Detaching the Diaphragm

- Exposure of T12-L1 may require detaching the diaphragm.
  - The diaphragm inserts and originates from the xiphoid and the inferior six ribs.
  - The lateral arcuate ligament arises from the transverse process of L1.
  - The crura extend more distally on the right.
  - The diaphragm is innervated centrally by the phrenic nerves.

- The patient is positioned in the lateral decubitus position with the right side down. The approach should be made from the left side to avoid the liver and inferior vena cava.
- The crura of the diaphragm are detached as described above.
- An oblique incision is made from the quadratus lumborum to the lateral border of the rectus abdominis (TECH FIG 4).
  - This approach can be extended to L5 in most patients and even to S1 in those with low-riding iliac crests.
  - The subcutaneous tissue is incised and the fascia of the external oblique is divided.
  - The external and internal obliques, transverse abdominis, and transversalis fascia are incised.

- The surgeon starts at the costal angle and incises the costodiaphragmatic reflection until extraperitoneal fat is visualized.
- The diaphragm is divided off the anterior chest wall (TECH FIG 3). The surgeon should leave a 1- to 2-cm cuff of diaphragm on the anterior chest wall to allow for diaphragm repair at closure. To avoid diaphragm denervation, the diaphragm should be incised only at its periphery. The diaphragm is split up to the lateral arcuate ligament.
- The medial and lateral crura are detached, exposing the underlying peritoneum.
- The peritoneum is swept medially until the retroperitoneal space is visualized.
- The surgeon bluntly dissects and sweeps the fascia of Gerota medially to expose the spine and the overlying parietal pleura.
- The aorta and vena cava are identified.
- The surgeon can elevate the psoas muscle if needed.
- The parietal pleura is incised to expose the spine.

### THORACOABDOMINAL RETROPERITONEAL LUMBAR SPINE APPROACH FROM T10 TO L3

- The peritoneum is exposed and bluntly reflected anteriorly.
- The ureter is identified and reflected anteriorly with retroperitoneal fat.
- The vertebral bodies, psoas, and great vessels are identified.
- The genitofemoral nerve lies on anterior psoas muscle, and excessive traction should be avoided.
- The segmental vessels that lie over the middle of the vertebral bodies are identified and ligated.
- The psoas is bluntly dissected off the vertebrae and retracted laterally.
- The vertebral body, pedicle, and neuroforamen can be visualized.
**TECH FIG 4** • Thoracoabdominal approach. **A.** A curvilinear incision is made over the 10th rib and the muscle layers are identified. **B.** The retroperitoneal space is entered through the costal cartilage after removing the 10th rib. **C.** The light areolar tissue that signifies the retroperitoneal space is identified, and the peritoneum is mobilized from the undersurface of the diaphragm and abdominal wall as well as the aorta. **D.** Exposure of the spine is done after ligation of segmental vessels.
### PEARLS AND PITFALLS

|                          | ![Detaching the psoas muscle off the transverse processes can improve exposure of the intervertebral disc space and neuroforamen. The transverse processes can also be removed to further increase exposure.](image)
|                          | ![Flexing the patient’s hips can decrease tension on the psoas and improve visualization of the lumbar spine.](image)
|                          | ![More ribs may need to be excised to gain better exposure, especially in older patients, in whom the ribs may not be as compliant to the rib spreader.](image)
|                          | ![From T2 to T5 it may help to detach the serratus anterior muscle from the anterior chest wall and reflect it cephalad to gain better exposure. The surgeon should avoid cutting the long thoracic nerve at this level.](image)
|                          | ![If scapular manipulation is needed to gain better exposure, the rhomboids, trapezius, and dorsal scapular muscles can be divided, allowing the scapula to be mobilized laterally.](image) |
| Visceral injury          | ![When approaching from the right side, the surgeon should dissect the soft tissues away from the spine as close as possible to the bone with a blunt gauze or finger to prevent injury to the cisterna chyli and thoracic duct.](image) |

### POSTOPERATIVE CARE
- Chest tubes are left in place until output is less than 150 mL over 24 hours.

### COMPLICATIONS
- The exiting nerve root can be injured while removing the pedicle.
- Vascular injury
- Intercostal neuralgia
- Atelectasis
- Neurologic injury
- Wrong-level surgery
- Significant bleeding can be encountered when entering the epidural space.
- Visceral injury

### REFERENCE
Anterior Lumbar Approach

P. Justin Tortolani, Samer Saiedy, and Ira L. Fedder

DEFINITION
- The anterior lumbar approach provides excellent access to the lumbar spine extending from the L2–3 disc to first segment of the sacrum (S1).

ANATOMY
- The anterior abdominal wall has a layered configuration that changes depending on whether the approach is proximal or distal to the arcuate line.
- Above the arcuate line, the layers in order are skin, subcutaneous fat (containing fascia of Camper and Scarpa), anterior rectus sheath (aponeurosis of the external and internal oblique muscles), rectus muscle, posterior rectus sheath (aponeurosis of the internal oblique and transversus abdominis muscles), transversalis fascia, and peritoneum (FIG 1).
- Below the arcuate line, the posterior rectus sheath is not present, and thus the rectus muscle lies directly on the transversalis fascia.
- For retroperitoneal exposures, the approach goes through the abdominal wall to the layer of the transversalis fascia and then progresses laterally until this fascia ends, exposing the retroperitoneal fat.
- For transperitoneal exposures, the transversalis fascia is divided in the midline, as is the peritoneum, and the exposure proceeds directly posteriorly to the level of the sacral prominence.
- The abdominal contents are retracted to expose the great vessels overlaying the anterior lumbar spine.
- Key anatomic structures with relationship to the spine are shown in FIGURE 2.
- Vascular
  - The abdominal aorta and the bifurcation into the left and right common iliac arteries lies anterior to the venous system, and the left iliac artery is typically encountered first (L4–5). In most people, the bifurcation occurs at L4–5.
  - Preoperative scrutiny of MRI or CT scans can help identify the location of the bifurcation, which can be important in planning.
  - The left renal artery and vein (L2) restrict exposure proximal to L2.
  - The inferior vena cava (IVC) lies posterior and to the right of the aorta. Because of this deep, right-sided position, the IVC should not be mobilized to the left.
  - The L5–S1 disc occupies a position between the bifurcation of the aorta and the IVC in most patients, so mobilization of the large vessels is rarely required for access. The middle sacral artery and vein branch off the left common iliac and should be ligated or cauterized if small.
  - Exposures above L5–S1, however, require mobilization of the great vessels to the right. To do this, the iliolumbar vein, which branches off the left common iliac, must be identified and ligated (see Techniques section).
- Genitourinary
  - Left kidney: rarely visualized, surrounded by perinephric fat (L1–2)
  - Left ureter: easily retracted anteriorly with peritoneal contents and can be identified by stimulated peristalsis
- Muscular
  - Psoas (paraspinal, L1–L5)
- Neurologic
  - Sympathetic chain (paraspinal, anterior and medial to psoas)
  - Presacral plexus (directly over sacrum)
  - Lumbosacral plexus (postero-medial to and within psoas muscle)
  - Genitofemoral nerve (lies on anterior aspect of psoas)
- Lymphatic
  - Paraspinal lymphatics and lymph nodes
  - Lymphatic drainage will appear as a milky white fluid, which is rarely of clinical consequence.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Previous abdominal surgery (eg, hysterectomy, hernia repair) can create challenges during this exposure. The presence of midline abdominal mesh, cellulitis or abscess, and a colostomy are relative contraindications to the anterior approach.
- Previous exposure of the anterior lumbar spine, particularly if it involved mobilization of the great veins, makes revision approaches much more risky due to the greater likelihood of vascular injury.
- Obesity (body mass index above 40) is a relative contraindication to anterior exposure of the lumbar spine due to the depth of the operative field.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs are used to assess the degree of aortic calcification and lumbopelvic deformity.
- Preoperative axial MRI or CT allows for estimation of the level of the bifurcation of the aorta and IVC (FIG 3).
- Routine angiography, CT-angiography, or MR-angiography is not necessary unless there is a concern for aberrant anatomy (eg, history of situs inversus).
- Preoperative arteriograms, venograms, and prophylactic IVC filters should be considered before any revision approaches to the anterior lumbar spine. Preoperative ureteral stents can also help prevent ureteral injury during revision exposure.

SURGICAL MANAGEMENT
- Indications for the anterior lumbar approach are as follows:
  - Anterior discectomy for interbody fusion, total disc replacement, disc débridement in cases of discitis and vertebral osteomyelitis, radical discectomy for deformity correction
Anterior corpectomy for tumor resection, radical deformity correction, and vertebral body osteomyelitis

Preoperative Planning

When exposure of the L5–S1 disc is required, the direct anterior lumbar approach should be used in most cases, as the ilium blocks satisfactory access from a lateral approach.

The direct anterior approach is less morbid than the lateral approach to the lumbar spine because the latter involves greater division of the abdominal wall musculature. For these reasons, we prefer the direct anterior approach (versus the lateral approach) even in cases of multilevel disc exposures (eg, lumbar scoliosis correction) unless the L1–2 disc or L2 vertebra requires exposure, or if anterior instrumentation in the form of screw–rod constructs is needed. Anterior plates can be used from a direct anterior approach at L5–S1 and in some cases L4–5, depending on the vascular anatomy. However, greater mobilization of the great vessels at the level of the bifurcation is needed from a direct anterior versus lateral approach. Thus, a lateral approach may provide better...
exposure to the spine if the great vessels are anticipated to be difficult to mobilize.

Positioning
- The patient is positioned supine over an inflatable pillow (FIG 4A).
- The operating room table should allow for free passage of the fluoroscopic C-arm (FIG 4B).
- Care should be taken to ensure that the pelvis is level so that true anteroposterior and lateral fluoroscopic images can be easily obtained.
- The patient’s arms can be tucked at the side, placed into a “cross” position, or crossed over the chest but must not restrict appropriate fluoroscopic imaging (FIG 4C).

Approach
- Various skin incisions can be used.
  - The Pfannenstiel can be used for L5–S1 exposures but is less extensile if additional proximal exposure is necessary.
  - The direct midline and paramedian incisions are useful for multilevel exposures as they are easily extended proximally or distally (FIG 5A–D).
  - Palpation of the sacral promontory allows more accurate placement of the skin incision (FIG 5E). Alternatively, a lateral C-arm view can be taken to mark the location of the incision, keeping in mind that the trajectory needed to access the disc, especially at L5–S1, may require that the incision be placed where the path of this trajectory meets the skin rather than directly over the disc space itself.
  - Retroperitoneal versus transperitoneal
    - The transperitoneal approach carries a higher risk of retrograde ejaculation due to the theoretically greater likelihood of injury to the presacral sympathetic nerve fibers.
    - This approach is useful, however, in revision approaches to L5–S1 in which the retroperitoneal exposure was used at the index procedure.
    - Transperitoneal approaches likely increase the risk of adhesion formation and possible small bowel obstruction. In addition, small or large bowel perforation and postoperative ileus are relatively more likely when the peritoneum is entered. Finally, extra time and care are required to retract the small intestines; this generally requires more retractors and large sponges to prevent interference during the remainder of the procedure.
  - Right versus left retroperitoneal
    - With certain failures of lumbar disc replacement, revision exposures of the lumbar spine are necessary. To preserve the left retroperitoneal exposure for a potential revision exposure, some surgeons advocate performing a right-sided retroperitoneal incision at the index surgery.
    - Because optimal placement of a lumbar disc correlates with improved functional outcomes for the patient, we advocate performing the exposure that provides the ideal set of circumstances for accurate device placement at the outset.5
    - Because the right common iliac artery and vein lie more vertical, crossing the L5–S1 disc space, whereas the left common iliac artery and vein traverse the disc diagonally, access to L5–S1 is easier and provides a more expansive exposure when performed from the left retroperitoneal approach.
Chapter 4  ANTERIOR LUMBAR APPROACH

ANTERIOR EXPOSURE OF LUMBAR SPINE (LEFT PARAMEDIAN INCISION AND RETROPERITONEAL APPROACH)

Dissection
- Once the skin is incised, the subcutaneous fat is divided in line with the skin incision to the level of the anterior rectus sheath.
- The anterior rectus sheath is identified and stripped clean of all fat to assist in identification of the fascial edges at the time of wound closure (TECH FIG 1A).
- The anterior rectus sheath is incised in line with the skin incision—centered over the disc of interest—and then retracted laterally, exposing the underlying rectus abdominis muscle (TECH FIG 1B).
- The rectus abdominis is then retracted laterally, exposing the underlying transversalis fascia (TECH FIG 1C).
- With the rectus abdominis retracted, the transversalis fascia is followed laterally to its insertion on the abdominal wall. A sponge on a stick can be used to gently strip the transversalis fascia off this insertion (TECH FIG 1D).
- Handheld retractors are then used to sweep the peritoneum and left ureter to the midline and beyond, to the patient’s right.

Further Exposure
- If exposure of L4–5 is required, the arcuate line is identified and a small, 1-inch incision is created to allow more freedom in mobilization of the peritoneum (TECH FIG 2A,B).
- For exposure of the L4–5 disc or above, the lateral border of the left common iliac artery and vein are first identified using blunt dissection. These vessels are then retracted toward the midline to expose the iliolumbar veins coursing posteriorly (TECH FIG 2C).
- There is often more than one iliolumbar vein, and retracting the common iliac too forcefully can result in avulsion and significant bleeding that can be difficult to control, especially if the wound is deep or the distal end of the vein retracts behind the psoas after avulsion.
- At L5–S1, blunt dissection with a Kittner exposes the disc space and defines the vascular anatomy. Palpation of the sacral promontory helps guide the blunt dissection.
TECH FIG 1 • A. The anterior rectus sheath can be clearly visualized. A small Richardson retractor has been placed at the top of the incision and a cerebellar retractor has been placed inferiorly. The blue arrow marks the center of the planned vertical fascial incision. B. The vertical fibers of the rectus abdominis muscle are visualized as the anterior rectus sheath is held to the patient’s left with two Kocher clamps. C. The rectus abdominis muscle is retracted laterally with a Kittner, exposing the underlying transversalis fascia. D. A sponge on a stick is used to bluntly dissect the transversalis fascia off the undersurface of the rectus.

TECH FIG 2 • A. For exposures at L4–5, the posterior rectus sheath (arcuate line) is identified and the peritoneum is retracted away. B. Once the arcuate line is identified, it can be cut vertically; this enables the surgeon to safely retract the abdominal contents to the patient’s right. C. In this cadaveric dissection, the iliolumbar veins can be visualized branching off the left common iliac vein, coursing posteriorly and laterally. By retracting the vein toward the midline and the psoas muscle laterally, the vein takes on a more transverse orientation and is easier to ligate. One of the lumbar nerve roots can be seen directly lateral to the iliolumbar vein. Excessive retraction pressure can injure these nerve roots. The arterial system has been removed.
Retractor Placement

- While a vascular surgeon or assistant retracts the great vessels with handheld retractors, sharp, narrow Hohmann retractors are placed directly into the vertebrae.
- Alternatively, blunt radiolucent retractors can be used. These retractors can be held by hand, can be fixed with transfixion pins, or can be clipped to an external frame (Omni) or ring (Endo-ring) for the remainder of the procedure.
- The optimal configuration of retractors for L5–S1 and L4–5 exposures is depicted in TECHNIQUES FIGURE 3A,B.
- At L5–S1, placing a malleable retractor against the sacrum keeps the peritoneal contents and bladder out of the operative field and also provides a safety barrier to inadvertent movements of surgical instruments.
- For L5–S1 exposures, we prefer to use a sharp Hohmann retractor, which penetrates the bone on the (patient’s) left side of the inferior vertebral body of L5. This ensures that the left common iliac vein will not slip under the retractor. Since this retractor is embedded in bone, there is no retraction on the lumbar nerve plexus.
- For L4–5 exposures, since there are no vascular structures to retract on the (patient’s) left side, a handheld retractor can be used to gently retract the psoas muscle. With a handheld retractor, it is critical that the blade does not extend too deep along the lateral edge of the vertebra, where it can impinge on the lumbar plexus. Surgical assistants need to pay attention to the force and location of their retraction effort.
- At L5–S1, retractors are positioned to retract the right and left common iliac artery and veins lateral to the superior margin of the disc.
- Before incising the disc, lateral fluoroscopic imaging should confirm the operative level and ensure that the retractors have not pierced the endplate (TECH FIG 3C).

**TECH FIG 3**

- **A.** Optimal configuration of retractors for exposure of the L5–S1 disc.
- **B.** Optimal configuration of retractors for exposure of the L4–5 disc. Thin Hohmann retractors with sharp tips can be used to pierce the vertebral body and keep the great vessels out of the operative field. Handheld radiolucent blade retractors can also be used to retract the great vessels. Some retractors are cannulated, allowing them to be fixed with a transfixion pin into the vertebral body.
- **C.** The lateral fluoroscopic image confirms that the teeth of the Hohmann retractors are not in the disc space and that they are surrounding the disc of interest.
**POSTOPERATIVE CARE**

- The patient is given 24 hours of antibiotics for wound infection prophylaxis.
- A perioperative nasogastric tube is used to reduce the incidence of postoperative ileus.
- The patient is mobilized on postoperative day 1 with a lumbar corset.
- Incentive spirometry is used.
- Skin staples are removed on postoperative day 10 to 14.
- Stool softeners and laxatives are used as needed to avoid fecal impaction.

**OUTCOMES**

- The prevalence of major vein lacerations was 1.4% and the prevalence of left iliac artery thrombosis was 0.45% in a series of 1315 consecutive retroperitoneal exposures.²
- Ureteral and nerve injuries (lumbosacral nerve root or sympathetic) occur less frequently than major vascular injuries.⁴
- Mortality after anterior lumbar exposures is less than 1%.⁴
- Anterior approaches to the spine likely result in reduced patient satisfaction in terms of self-image and appearance.³
- The possibility of retrograde ejaculation should be discussed preoperatively with all male patients, as the prevalence ranges from 0.1% to 13.3%.¹⁶ To preclude the need to harvest sperm from the bladder in affected men, donation before surgery is a viable option.

**COMPLICATIONS**

- Retrograde ejaculation
- Ureteral injury
- Abdominal or umbilical hernia
- Wound infection and dehiscence
- Bowel injury
- Bladder injury
- Lumbosacral plexus injury
- Deep venous thrombosis and pulmonary embolism
- Major vessel injury and massive blood loss
- Reflex sympathetic dystrophy

**REFERENCES**

ANATOMY

Superficial landmarks allow for gross determination of anatomic level. Proximally, C7 and T1 are the largest spinous processes and act as landmarks for determining anatomic level. Distally, the intercrestal line approximates the L4–5 interspace.

There are three layers to the posterior musculature of the spine (FIG 1, Table 1):

- Superficial layer: trapezius, latissimus dorsi, rhomboid major and minor, and levator scapulae
- Intermediate layer: serratus posterior superior and inferior, and levatores costarum
- Deep layer: erector spinae, transversospinalis, interspinalis, and intertransversarii

The superficial and intermediate layers receive their nervous supply from peripheral nerves, which are not encountered through the posterior approach (FIG 2). The deep layer receives its nervous supply segmentally from the posterior dorsal rami. There is a large amount of redundancy in the innervation of the deep layer.

The midline approach is a true internervous plane, and nerve injury occurs only with excessive lateral dissection.

The vascular supply to the deep layer is from segmental branches of the aorta. These vessels enter the operative field at the level of the intertransverse ligament and can be a source of significant bleeding.

The facet joint capsules have a shiny white appearance, with the individual fibers can be seen inserting onto the lateral edge of the laminar trough. Care should be taken to avoid violating the capsular fibers unless that segment is being fused.

The ligamentum flavum has a yellow appearance, with the fibers running in a cephalad-caudad direction. The cephalad end of the ligament has a broad insertion from the base of the spinous process to between 50 and 70 percent of the anterior surface of the lamina. The caudad end of the ligament inserts from the superior edge of the lamina to between 2 and 6 mm of the anterior surface of the lamina.

Particularly at the L5–S1 level, the interspace may be widened or the posterior bony anatomy only partly formed. Care should be exercised when exposing this level as inadvertent plunging into the canal may occur.

Laterally, the intertransverse membrane overlies the iliopsoas and protects the neural structures that lie beneath.

In children, the spinous process apophysis has not fused. During dissection, the apophysis is split down to the bone and then elevated with the paraspinal musculature.

SURGICAL MANAGEMENT

Positioning

- Patients should be placed in the prone position on a radiolucent table (FIG 3A).
- Care is taken to ensure that the neck is in a neutral position with no hyperextension.
- The arms are positioned at 90 degrees or less of abduction to minimize the likelihood of rotator cuff impingement. The arms are allowed to slightly hang down in a forward-flexed position about 10 degrees. The axilla should be clear from any padding to prevent brachial plexus palsy.
- Elbow pads are placed along the medial epicondyle to protect the ulnar nerve.
- Pads are placed at the chest and iliac crests.
- The chest pad is placed just proximal to the level of the xiphoid process and distal to the axilla. In women, care is taken to tuck the breasts and ensure that the nipples are pressure-free.
- The iliac pads are placed two fingerbreadths distal to the anterior superior iliac spine, allowing the abdomen to hang free and reducing any unnecessary epidural bleeding.
- Proper placement of the chest and iliac pads allows for restoration of normal sagittal alignment via gravity.
- Alternatively, for lumbar decompressive procedures alone, the knees are positioned in a sling, allowing the hips to flex and eliminating lumbar lordosis and widening the laminar interspaces (FIG 3B). This position improves access to the lumbar spinal canal but should be avoided when instrumenting as lumbar lordosis is decreased.

**Approach**
- Two approaches are used: midline and paraspinal.
- The midline approach is used for most spinal procedures as it allows direct access to the spinal canal.
- The paraspinal approach, also known as the Wiltse approach, was initially described for spondylolisthesis but is now being used during far-lateral discectomies and minimally invasive muscle-sparing techniques.
- There is increased interest in the paraspinal approach, particularly in conjunction with transforaminal lumbar interbody fusion procedures.
MIDLINE POSTERIOR APPROACH

Incision and Dissection

- Anatomic landmarks are identified to center the skin incision appropriately (TECH FIG 1A).
- A midline incision is made over the spinous processes down to the level of the fascia.
- A Cobb elevator is used to create 2-mm full-thickness skin flaps with subcutaneous fat. This allows for better visualization of the fascia during closure (TECH FIG 1B,C).
- The location of the spinous processes is again verified, and electrocautery is used to reflect the fascia from the tips of the spinous processes.
- Electrocautery is used to subperiosteally elevate the paraspinal musculature laterally to the trough of the lamina. The surgeon should avoid going beyond this point to protect the insertion of the facet joint capsule.

Cautery

- Two venous bleeders are encountered that require electrocautery (TECH FIG 2A).
  - The first is located adjacent to the pars interarticularis (TECH FIG 2B,C).
  - The second is located just lateral to the facet joint.
- Electrocautery is used to elevate the paraspinal musculature off the transverse processes. Care should be taken to stay on the transverse process and not to violate the intertransverse membrane.
- Bipolar cautery should be used at the intertransverse ligament to avoid damage to the spinal nerves.
Paraspinal Resection

- In large and muscular patients, often it is necessary to excise a portion of the paraspinal muscles overlying the transverse processes to be fused.

- The muscle is resected beginning underneath the fascia and extending toward the lateral edge of the transverse processes. This creates a pocket over the transverse processes that serves as a bone graft cavity (TECH FIG 3).

**TECH FIG 2** • A. Venous bleeding sites are adjacent to the pars interarticularis and at the junction of the facet and the transverse process. B,C. Probes (arrows) indicate the location of venous bleeders adjacent to the pars interarticularis (B) and the facet joint (C).

**TECH FIG 3** • A,B. Electrocautery is used to excavate a muscular pocket for the fusion mass. C,D. Complete posterior exposure.
**PARASPINAL APPROACH**

- The approach is typically performed two fingerbreadths lateral to the spinous process.
- After the fascia has been exposed, the paraspinal muscles are palpated and the interval between the multifidus medially and longissimus laterally is identified.
- A sharp incision through the fascia is made at this interval (TECH FIG 4).
- The interval is defined with blunt dissection down to the lateral edge of the facet joint and transverse process junction.

**TECH FIG 4** • Cross-section of spine showing Wiltse interval.

DEFINITION
- Cervical spondylosis refers to degenerative conditions affecting the cervical spine, including disc degeneration, herniation, facet arthrosis, and osteophytic spur formation. Depending on the nature and location of the spondylotic changes, pathologic compression of neural structures in the cervical spine may occur.
- This chapter focuses on anterior cervical discectomy and fusion (ACDF) as a surgical treatment option for patients with cervical radiculopathy. Cervical myelopathy can also be treated with ACDF as long as the spinal cord compression occurs at the disc, rather than the retrovertebral, level.
- All techniques described in this chapter can apply to the decompression of the spinal cord in myelopathic patients as well as the nerve root in radiculopathic patients. However, for the purposes of organization, cervical myelopathy is discussed in the chapter on anterior cervical corpectomy (see Chap. SP-7).

ANATOMY
- The anterior longitudinal ligament is a wide band of ligaments stretching along the anterior surface of the vertebral bodies. Its dense longitudinal fibers widen as they travel caudally and are intimately associated with the intervertebral discs as well as the vertebral endplates.
- The posterior longitudinal ligament (PLL) is a smooth and shiny group of dense ligaments that course along the posterior surface of the vertebral bodies within the spinal canal. The PLL tends to be thicker centrally and thins out laterally as it attaches to the uncinate regions. Bulging or ossification of the PLL (OPLL) can cause spinal cord compression.
- The intervertebral disc comprises the outer annulus fibrosus and the central gelatinous nucleus pulposus. Each disc is attached to the subchondral bone of the adjacent vertebral bodies. The outermost rim of the vertebral endplate is not attached to the disc, leaving a ring of exposed bone that may be more prone to forming arthrotic spurs.
- The uncovertebral joints are critical bony landmarks for anterior cervical decompression (FIG 1). Spurs commonly arise from these articulations and cause impingement of the exiting roots as they enter the foramen.
- Depending on the cervical level, the vertebral artery may be as close as 5 mm away from the medial aspect of the uncinate process.
- Each cervical spinal nerve is composed of dorsal and ventral roots. The ventral root lies dorsal to the uncovertebral joint, while the dorsal root is ventral to the superior articulating facet.
- It is important to keep in mind when performing uncovertebral osteophyte resection that the nerve root leaves the spinal cord at roughly a 45-degree angle ventrolaterally in the

FIG 1 • Anterior foraminotomy anatomy: important anatomic relationships to consider when performing anterior cervical spine surgery. The exiting nerve root enters the foramen at a 45-degree ventrolateral angle. The posterior aspect of the uncinate joint marks the entry zone of the neuroforamen, and it is where osteophytes commonly arise to impinge the exiting root. Thus, the uncus should be decompressed when performing foraminotomy. It is critical to hug the posterior aspect of the uncinate during foraminotomy to avoid injuring the exiting root, which lies immediately dorsal. The vertebral artery is unlikely to be injured while working in the posterior disc space (eg, during decompression) because it is located at roughly the level of the middle third of the vertebra. The trajectory of discectomy should be bounded by the uncines at all times, but it can widen posteriorly at the level of the nerve root to thoroughly decompress the root while avoiding vertebral artery injury (dashed blue line). The posterior longitudinal ligament (dashed yellow line) tends to be thicker and better defined centrally; it thins out laterally.
axial plane. Thus, care must be taken to hug the posterior surface of the uncinate to avoid injury to the exiting root.4

**PATHOGENESIS**
- Neural impingement occurs in two main locations: within the spinal canal, affecting the spinal cord, the nerve root, or both; or within the foramen, where the exiting root can be affected.
- Depending on whether the involved structure is the spinal cord or the nerve root, patients can present with symptoms of myelopathy, radiculopathy, or both.

**NATURAL HISTORY**
- The natural history of cervical radiculopathy is generally favorable, with most patients having spontaneous resolution or considerable improvement of their symptoms over time.
- It is not common for radiculopathic patients to progress to myelopathy.9,10

**HISTORY AND PHYSICAL FINDINGS**
- Patients with radiculopathy typically present with radiating pain, paresthesia, or motor weakness (Table 1). However, the pattern of symptoms is not always dermatomal (FIG 2).
- On examination, patients with radiculopathy may have motor, sensory, or reflex changes along the affected nerve root distribution. However, the neurologic examination findings may be normal.
- Patients may express exacerbation of radicular pain with particular head positions (ie, head positions that narrow the size of the neural foramen, such as neck extension with rotation to the affected extremity).
- This can be elicited by performing the Spurling test. The Spurling sign is very helpful in differentiating cervical radiculopathy from extraspinal causes, such as cubital or carpal tunnel syndromes, as reproduction of symptoms should occur only with a cervical source of compression.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs, although of limited value in evaluating neural compression, remain a commonly acquired initial study and can be used to evaluate overall alignment, spinal instability, or bony pathology, including spur formation.
- MRI is the modality of choice for evaluating neural compression.
- CT-myelography provides outstanding resolution of bony and neural anatomy, but it is less appealing as it requires an invasive procedure. It is typically recommended for patients with contraindications for MRI (eg, prosthetic heart valve, pacemaker) or when MRI fails to provide sufficient detail.

If a high-quality MRI is available but questions remain regarding bony anatomy for the purposes of surgical planning, a noncontrast CT scan provides complementary information (eg, differentiating OPLL from disc herniation) (FIG 3).

**DIFFERENTIAL DIAGNOSIS**
- Cervical radiculopathy
- Cervical myelopathy
- Brachial plexus injury
- Complex regional pain syndrome or reflex sympathetic dystrophy
- Thoracic outlet syndrome
- Inflammatory arthropathy
- Spinal cord tumor
- Angina

![FIG 2 • Dermatomes of the cervical nerve roots. Symptoms do not always follow the textbook distribution of dermatomes. In particular, radiculopathies involving various nerve roots, such as C5, C6, or C7, can all produce periscapular pain, not uncommonly in the absence of radiating pain down the arm. If in doubt as to the offending level, a selective nerve root block can be performed for diagnostic purposes.](image-url)
Shoulder pathology
- Peripheral nerve compression (eg, carpal or cubital tunnel syndrome)
- Diabetic neuropathy
- Multiple sclerosis
- Syringomyelia
- Stroke
- Guillain-Barré syndrome
- Normal-pressure hydrocephalus
- Spinal cord tumor

NONOPERATIVE MANAGEMENT
- Nonoperative management should be considered as the initial mode of treatment for most patients with radiculopathy.
- Nonsurgical treatment typically includes physical therapy, traction, pain medication, cervical collars, and epidural injections.

SURGICAL MANAGEMENT
- Surgical intervention is indicated for radiculopathy in patients with persistent symptoms resistant to nonoperative care, progressive weakness, or instability.
- Common surgical approaches to radiculopathy include ACDF versus posterior laminoforaminotomy.¹¹

Preoperative Planning
- The surgeon should evaluate imaging studies for anatomic variations, such as medial aberrancy of the vertebral artery.
- To perform a safe but complete and adequate neural decompression, high-quality illumination and magnification are essential.
- An operating microscope provides illumination and visualization superior to that of loupes and headlights, but either method can be used.
- Another advantage to the microscope is that the view obtained by the assistant is the same as that of the operating surgeon.
- If the surgeon chooses to use the microscope, given the smaller field of view, it is imperative to continuously adjust the viewing angle such that a line of sight parallel to the disc space is achieved (FIG 4). If this is not done, the surgeon may inadvertently stray away from the disc space, veer into one vertebral body or the other, and not proceed to the back of the disc space, where the decompression needs to occur.

Positioning
- The patient is positioned with a bump under the scapula and the occiput on a foam doughnut to prevent pressure necrosis.
- The amount of extension tolerated preoperatively without excessive pain or neurologic symptoms is recreated.

Approach
- A standard Smith-Robinson approach to the anterior cervical spine is used for most cases from C2 to T2.

FIG 3 • MRI and CT scans may provide complementary information in delineating bony versus soft tissue masses. A. On the axial MRI, the compressive lesion appears to be a soft disc. B. A CT scan through the same level, however, demonstrates the pathology to be an ossified disc. Similarly, CT scans can help differentiate disc herniations from ossification of the posterior longitudinal ligament.

FIG 4 • Line of sight. When using the microscope, it must be angled properly to provide a parallel view of the disc space to facilitate decompression and endplate preparation. Endplate preparation should proceed in a parallel fashion (dotted red lines) (A) centered on the disc space to achieve a rectangular space for graft insertion. Parallel, wide preparation of the disc space also makes decompression easier to perform and ensures that the decompression is centered on the disc space (C). (B,C)
- If the line of sight is not maintained, one may err into the vertebral bodies above and below rather than progressing toward the area at the disc level that requires decompression. To achieve parallel surfaces, the inferior endplate of the cephalad vertebra typically requires greater preparation because it is concave. In contrast, the superior endplate of the caudal vertebra is flatter and requires less preparation. (C) Proper line of sight is facilitated by removing the anterior lip (arrow, shaded yellow), which allows for better visualization of, and access to, the posterior disc space.
Initial Discectomy

- Once the disc is exposed, it is sharply incised with a no. 15 blade and removed with a combination of curettes and pituitary rongeurs.
- The disc and cartilaginous material should be removed until the PLL and both uncinate processes are visualized (TECH FIG 1A).
- An important maneuver to facilitate disc space visualization and neural decompression is to remove the anterior portion of the inferior endplate of the superior vertebral body (the anterior lip). Doing so provides a direct line of sight into the posterior disc space, which facilitates later foraminotomy and resection of the PLL, if necessary.
- This surface is almost always concave, with the anterior portion overhanging the disc space, thus preventing direct visualization of the posterior disc space.
- Removal can be done with either a Kerrison rongeur or a high-speed burr.
- Flattening this surface also facilitates optimal graft–endplate contact (TECH FIG 1B,C).
- Use of the burr to fashion the endplates, alternating with use of the curettes and pituitary rongeur to remove cartilage and disc material, is performed.

Use of Distraction: Pins, Tongs, and Spreaders

- Intervertebral body distraction pins can be placed to gently distract the disc space and improve visualization.
- Generally, this is done after an initial superficial discectomy, which allows greater disc space mobilization with the pins.
- Because greater preparation of the inferior endplate of the superior vertebra is usually needed, the Caspar pin should be placed more cephalad in the cephalad vertebral body (TECH FIG 2).
- Overdistraction of the disc space is not desired. If the disc space is fused in an overdistacted position, postoperative neck pain may result. If there is a significant compressive lesion on the spinal cord, distraction should

**TECH FIG 1 • A.** The discectomy should begin lateral (red lines) to the medial border of the uncinate. The upslope of the uncinate is clearly defined with curettes and Kerrison rongeurs until these borders are unquestionably identified. Having a wide discectomy allows for placement of larger grafts or supplemental grafts in the uncinate regions. **B,C.** Anterior cervical discectomy and fusion graft carpentry. Creating parallel disc spaces facilitates graft–host bone contact, securing an intimate fit, as well as allowing for wide decompression of spurs arising from the posterior disc space. Spurs are removed off the inferior vertebral of C5 and C6 (arrows). More bone than usual was removed from the inferior portion of C6 because of the extensive spondylotic bar causing spinal cord compression along the floor of the canal in this patient.

**TECH FIG 2 •** Caspar pin placement. Because greater preparation of the inferior endplate on the cephalad vertebra is necessary, the surgeon should place the upper Caspar pin (C5) further away from the endplate (eg, in the midbody of C5 or more cephalad), while being cognizant of not entering the adjacent disc space above. The Caspar pins are placed in the midline to avoid compromising later screw fixation during plating. To achieve parallel distraction, the pins should be placed parallel to the disc space. If the tips (ie, the leading ends) converge, relative kyphosis of the disc space occurs with placement of the Caspar pin spreader and distraction; if the tips diverge, relative segmental lordosis occurs with placement of the Caspar pin spreader and distraction.
be avoided until the compression has been relieved to prevent stretching or tenting of the cord over that lesion.

- An additional benefit of the Caspar pins is that they help to retract the soft tissues in a cephalad-caudal direction without the use of a secondary set of retractor blades.
- Alternatively, a small laminar spreader can be used in the contralateral disc space instead of Caspar pins to provide distraction.

**Endplate Preparation**

- The inferior endplate of the cephalad level is concave, whereas the superior endplate of the inferior level tends to be relatively flatter. Thus, to achieve intimate contact of bone graft with both endplates, a rectangular space is created by parallel decortication of the endplates.
  - This generally requires greater preparation of the inferior endplate of the cephalad level versus the superior endplate of the inferior level.
- It is important not to remove too much bone off the inferior endplate of the cephalad level, however, as doing so limits the bone available in the vertebra to accommodate a plate and screws. This is particularly the case in smaller patients who have smaller vertebrae.
- A high-speed burr is helpful in decorticating the endplates.
- The creation of a parallel rectangular space within the disc space allows insertion of a graft appropriately sized to match the larger height present at the center of the disc space.
- Both endplates should be thoroughly denuded of cartilage and decorticated to reveal bleeding bony surfaces to enhance the chance of successful fusion.\(^5\)
- Alternating use of the high-speed burr, curettes, and the pituitary rongeur will allow the surgeon to reach the posterior disc space and the PLL.
- During ACDF, we are more aggressive with endplate preparation than during corpectomy, because ACDF grafts tend to be more stable than corpectomy grafts.
  - If major endplate resection is performed during corpectomy, significant settling or pistoning of the graft may occur (see Chap. SP-7), which is less likely with ACDFs. Furthermore, in cases of extensive spondylosis, wide disc space preparation facilitates decompression along the floor of the canal in ACDF surgery.
  - When performing corpectomy, on the other hand, the additional room is not usually necessary because removing the vertebral body creates wide access for work at the disc level.

**Anterior Foraminotomy**

- The discectomy is performed to the level of the PLL, with complete removal of the posterior annulus. It is safer to leave the PLL intact during the initial foraminotomy or resection of posterior osteophytes when the burr is being used, because it acts as a protective layer to the neural elements. Once the bony removal is complete, the PLL can then be resected.\(^2\)
- The medial half of the posterior uncinate is thinned under direct visualization with a high-speed burr to unroof the entry zone of the foramen (TECH FIG 3).
  - The microscope is angled appropriately to visualize the uncinate.

**TECH FIG 3** • Anterior foraminotomy. **A.** The burr is used to thin down bone in the lateral aspect of the canal (arrow) until only a thin shell is left. The posterior longitudinal ligament (PLL) is left intact as a protective layer to the neural elements until burring is completed. **B.** A curette is used to outline the bony edges and ensure that they are thin enough for passage of a curette or Kerrison rongeur. The PLL does not necessarily need to be resected during foraminotomy if the pathology is due solely to uncinate bone spurs, although we routinely do so and do not consider the decompression complete until the lateral edge of the dura and the exiting root are clearly visualized and palpated to be free of compression. **C.** A 2-mm Kerrison is then used to remove bone spurs. It is critical to hug the posterior margin of the uncinate during this move to avoid injuring the root underneath, which exits the canal ventrolaterally at about a 45-degree angle.

- In general, it is easier to decompress the contralateral rather than the ipsilateral foramen, although decompression of both is certainly possible. Thus, in cases of unilateral radiculopathy, we prefer to approach the spine from the side opposite to the patient’s symptoms.
- It is important not to force a large instrument into a severely narrowed foramen if it does not fit easily. Instead, the surgeon should use the burr to thin the uncus until the instrument can easily be passed into the foramen.
- Constant irrigation is performed to prevent thermal injury and to clear away bone debris.
- If visualization is adequate, continued thinning of the osteophyte can progress until only a thin shell of bone is left.
- A microcurette or 2-mm Kerrison is then used to resect the thinned osteophytes.
Alternating between microcurettes or a Kerrison and the burr, the foramen can be gently and progressively carved out laterally.

- The nerve root exits the spinal canal at roughly a 45-degree angle, ventrolaterally. Thus, it is imperative to avoid blindly placing a burr, curette, or Kerrison deep to the uncinate to avoid root injury. Instead, one should closely hug the uncinate while entering and decompressing the foramen (see Fig 1).

- Foraminotomy is complete when a micro nerve hook or curette can easily be passed into the foramen anterior to the exiting root without resistance.

When and How to Resect the PLL

- With soft disc herniations, a defect in the PLL is often present through which the nuclear material extrudes (TECH FIG 4A,B).
- By delicately probing with a microcurette, the extruded fragment can be fished out from behind the PLL.
- If necessary, the defect in the PLL should be enlarged with a 2-mm Kerrison until a satisfactory portal is available to remove the herniation and ensure that all loose disc fragments have been removed.
- It is debatable whether the PLL needs to be resected in every case. In general, we prefer to do so, especially in cases of disc extrusion, and do not consider the decompression complete until the dural sac or exiting nerve root (depending on which is compressed based on preoperative imaging) is inspected for the absence of any further compression.

- If, however, the compressive lesion is an uncinate spur, with no evidence of subligamentous disc extrusion, satisfactory decompression can be achieved by removing the spurs without necessarily removing the PLL.

- If there is no rent in the PLL, one can be created by teasing a microcurette between the longitudinal fibers of the PLL until the curette is posterior to the PLL (TECH FIG 4C,D).

- Once the plane is identified between the PLL and dura, the fibers of the PLL can be resected with a curette or Kerrison rongeur.
- Placing tension on the PLL with gentle distraction will facilitate its removal.

**TECH FIG 4 A,B.** Removing herniated nucleus pulposus. A. With extruded herniations, a rent in the longitudinal fibers of the posterior longitudinal ligament (PLL) may be identified. A curette is then used to delineate the edges of the rent in the PLL. Once this is defined and the surgeon is certain of a plane between the PLL and underlying dura, a Kerrison is used to enlarge the edges of the rent. B. The rent has been enlarged to provide more room for finding the herniation. Curettes are then used to fish out the fragments and decompress the cord or root. C,D. Removing the PLL. C. If the PLL is intact, it can be removed by teasing in between the longitudinal fibers with a microcurette. Once a plane is established, a Kerrison can be used to remove the PLL. D. It is often easier to find this plane in the central portion of the PLL, where it is thicker, than laterally, where it is thinner and less defined.
We generally find it easier to define a plane in the PLL centrally, where it tends to be thicker, than laterally, where it is thinner and the plane with the dura is less distinct. Often, there are multiple layers of PLL, and usually in chronic cases there is a membranous layer between the PLL and the dural sac that can be confused with dura itself. In general, if it does not look like dura, it probably is not.

The portion of the PLL contralateral to the disc herniation or symptomatic foraminal stenosis does not routinely need to be removed.

**Avoiding Vertebral Artery and Neural Injury**

Before surgery, the surgeon should always scrutinize the position of the vertebral arteries on the preoperative scans to rule out the presence of aberrancies in their course (Tech Fig 5A,B,C).

Aberrations typically occur within the vertebral body. However, it is not uncommon for one vertebral artery to be closer to the uncinate on one side versus the other, which would mandate greater caution when approaching that side.

In the absence of vertebral artery aberrancy, laceration to the vertebral artery is most likely to occur from the surgeon’s loss of orientation to the uncinates. The uncinates define the safe zone for the vertebral artery and the effective zone for the decompression.

It is imperative to define and maintain orientation with both uncinates at all times during anterior cervical surgery.

The vertebral artery is typically in the anterior two thirds of the disc space. When curetting disc material in this area, a vertebral artery laceration might occur if the curette strays lateral to the lateral border of the uncinate.

If in doubt, a Penfield dissector can be used to identify the lateral border of the uncinate processes to avoid straying laterally and injuring the vertebral arteries, which are generally a few millimeters from the lateral edge of the uncinate (Tech Fig 5C).

**Graft Sizing and Placement**

Ultimate graft height can be estimated preoperatively from the preoperative lateral film. In many cases, a graft height of 2 to 3 mm more than that measured on the preoperative lateral film will be the optimal choice.

Ideally, the anteroposterior depth of the graft should be a few millimeters less than that of the disc space, such that the graft can be countersunk 2 mm without entering the spinal canal.

The final height of the graft can be determined after endplate preparation with sizers that accompany commercial grafts (Tech Fig 6).

The trials should be lightly malleted into position under gentle Caspar pin distraction.

A snug fit in the distracted position will ensure an excellent fit after removal of distraction pins.

If the trial does not fit but the next smaller trial seems too loose, the surgeon should identify the area of impingement and lightly decorticate that area. Then, the trial is reinserted.

**TECH FIG 5 A,B.** Vertebral artery anomalies. A. The right transverse foramen (arrow) courses somewhat more medially than the one on the left. This is a subtle but potentially important anomaly to observe preoperatively. B. The anomaly occurs within the vertebral body rather than at the disc space level, where the right transverse foramen is now more normally positioned (arrow). C. Penfield lateral to the uncinate. In certain cases, especially if there is a deformity, the location of the lateral border of the uncinate (ie, the safe zone for the vertebral artery) may not be obvious after elevation of the longus colli. Placing a Penfield 4 dissector gently underneath the longus colli, retracting it laterally, and then hooking the dissector lateral to the uncinate will allow for safe orientation to the vertebral artery.

**TECH FIG 6.** Commercially available sizers are used to determine optimal graft size. A trial that fits snugly under gentle Caspar distraction will suffice. If autograft is used, the appropriate trial is used as a template for cutting the autograft bone. The surgeon should try to place a graft that fills the space as much as possible without overdistracting, which can cause posterior neck pain, or entering the spinal canal.
For multilevel ACDF, we prefer to decompress and graft each segment before proceeding to the next level. One way to enhance fusion rates is to place as much bone into the interspace as possible. A wide decompression also provides greater room for bone graft. Space lateral to the structural bone graft in the uncinate regions can be packed with bone or bone graft substitutes. If the space is wide enough, two grafts can be placed side by side to fill the entire space. We generally prefer to use commercially prepared cortical allografts for ACDF, except in patients with poor healing potential. Alternatively, autograft iliac crest bone can be used.

Determining Plate Length
- Plating is optional for one-level ACDF with autograft. If allograft or multilevel surgery is performed, plating is recommended.
- Once the graft has been placed, the size of the plate is then determined.
- Optimal plate length is one that allows for the screws to be immediately adjacent to the endplates (TECH FIG 7).
- This plate length allows for screws that angle away from the disc space, which in turn allows for screws that are longer than ones directed parallel to the disc space, yet are short enough to avoid entry into the supra- and infra-adjacent disc spaces.
- This length also prevents impingement of the plate into the adjacent disc spaces.

Plating Techniques
- The plate should be contoured into lordosis to lie flush against the vertebral bodies.
- It should also be centered coronally within the margins of the uncinate processes.
- Screws should also be angled medially to decrease the chance of lateral injury to nerve roots or vertebral arteries.
- The screw length can be estimated preoperatively by measuring the depth of the vertebral body on CT or MRI scans. The majority of levels will accommodate 14- to 16-mm screws.
- Dynamic plates can be used if desired (TECH FIG 8). They have the theoretical benefit of improving load sharing on the graft. There are several types of dynamic plates.
  - Variable screw systems allow for toggling within a fixed screw hole with settling of the construct. A potential downside is that the screw can loosen within bone as toggling occurs.
  - Slotted plates have holes that allow screws to translate longitudinally as the construct shortens. The screws are rigidly fixed to bone and do not toggle, but excessive translation may lead to adjacent-level plate impingement.
  - Telescoping plates use fixed screws in nonslotted holes, but the ends of the plate telescope with respect to each other as settling occurs. Postoperative adjacent-level plate impingement will not occur with this design if the plate is properly positioned at the time of surgery, as the distance from the end of the

**TECH FIG 7** • Proper plate sizing. A. The length of an optimally sized plate is such that the screw holes at the top and bottom of the construct are immediately adjacent to their respective endplates. In this example, even though this was done, the plate is still closer to the cephalad adjacent disc space than ideal because the vertebral bodies in this patient are relatively short. Nevertheless, adjacent-level disc degeneration did not occur in this patient at 2-year follow-up. Bicortical screw purchase is not routinely needed, but estimates of screw length can be obtained by measuring MRI or CT scans preoperatively. Screws should be angled away from the disc space to provide greater length and divergent fixation, which may better resist pullout. B. This patient also has short vertebrae. However, this plate was placed too close to the adjacent disc, resulting in adjacent-level ossification disease (arrow). The cephalad screws are not immediately adjacent to the endplate but rather inserted at roughly the midpoint of the vertebral body. Similarly, the caudal screws begin in the midportion of the vertebral body. The plate is too long distally and comes close to the subjacent disc as well. As demonstrated by these examples, proper plate sizing is especially important in patients with shorter vertebrae, where the adjacent discs are closer together.
plate to the endplate does not change with construct shortening. However, these plates tend to be somewhat thicker.

- If dynamic plates are used, the surgeon must perform the plating procedure to accommodate the anticipated settling without overlapping uninvolved adjacent discs.\(^8\)

**ANTERIOR CERVICAL DISCECTOMY AND FUSION WITHOUT INSTRUMENTATION**

- **ACDFs** were traditionally performed without plating.
- Although plates may better preserve lordosis and achieve higher fusion rates in multilevel cases, avoiding plates may decrease operative time, decrease the amount of retraction on the soft tissue structures of the neck during surgery, and avoid plate-related complications such as screw backout or esophageal erosion.
- However, if one chooses not to use a plate, autograft should be used rather than allograft, and rigid postoperative immobilization in a cervical orthosis is mandatory.
- Up to three adjacent interbody cervical fusions can be safely performed without instrumentation.
  - The interspaces should be fused sequentially, meaning a decompression and fusion is completed at one interspace before the next is addressed.

**Measuring the Space**

- After appropriate decompression, the depth and height of the interspace are measured without distraction (TECH FIG 9A,B).
- A laminar spreader is then inserted to distract the interspace, and the height is again measured (TECH FIG 9C,D).
- Without distraction, the height is generally 6 mm; with distraction, it can be up to 12 mm.
- This distraction is important in shaping the tricortical graft. The height of the graft should be greater than the resting height but less than the distracting height so that the inherent compression of the vertebral bodies will hold the graft firmly in place.

**Inserting the Graft**

- After the appropriate size of cortical graft is obtained, it is inserted with the laminar spreader distracted (TECH FIG 10A,B).
- The graft should have at least a 2-mm offset anteriorly, and the posterior edge of the graft should be 4 mm anterior to the dura and PLL.
- After the distraction is released (Tech Fig 10C,D), the graft should be tested for stability by trying to dislodge it using a smooth right-angle probe.
- Postoperatively, if the graft is stable, a simple soft collar should be used for 4 to 6 weeks.
TECH FIG 9 • Measuring the interspace without (A,B) and with (C,D) distraction.

TECH FIG 10 • The cortical graft in place with (A,B) and without (C,D) distraction. Without distraction, the graft is compressed by the natural elasticity of the cervical spine. There is about 2 to 6 mm of free space between the posterior surface of the graft and the spinal cord.
The surgeon should create a rectangular space with parallel endplates. This will generally require removing the anterior portion of the inferior endplate to allow for better visualization of the posterior disc space, particularly in narrow spondylotic discs, and facilitates subsequent decompression.

**Foraminotomy**
- The uncinate is the guide to the foramen. The surgeon should maintain orientation to it at all times. When entering the foramen to remove bone spurs, the curette or Kerrison should hug the posterior aspect of the uncinate to avoid the nerve root, which exits ventrally at a 45-degree angle. The uncinate should be thinned first with a burr so that a small instrument can be inserted into the foramen to complete the foraminotomy without injuring the underlying root.

**Plate fixation**
- The surgeon should choose the shortest plate that will fit, such that the screw holes are immediately adjacent to the endplates, to avoid adjacent-level plate or screw impingement.

**Multiple fusions in ACDF without instrumentation**
- In cases of multiple fusions, each decompression and fusion must be completed before the next interspace is addressed. If all the interspaces to be fused are decompressed before the first graft is inserted, it will lead to unbalanced grafts, with one bone plug being significantly wider than the others because of the inherent elasticity of the vertebral bodies.

**POSTOPERATIVE CARE**
- The utility of bracing after plated ACDF is debatable.
- We typically place the patient in a cervical collar for 6 weeks.
- A deep drain is placed in the retropharyngeal space to prevent hematoma formation. It is typically removed the morning after surgery unless its output is greater than 30 cc in the last 8 hours.
- The postoperative diet may be rapidly advanced as tolerated. Cold beverages and ice cream may help with dysphagia and reduce swelling in the immediate perioperative period.

**OUTCOMES**
- Over 90% of patients experience excellent relief of radicular symptoms with ACDF.
- Midline axial neck pain may improve if it is associated with radicular pain, but patients should be counseled that the primary goal of treatment is neural decompression and relief of radicular or myelopathic symptoms.
- Similarly, unilateral neck pain can be a manifestation of radiculopathy and also generally improves.
- However, isolated axial neck pain without radicular complaints does not predictably improve with surgery, and we recommend nonoperative treatment in such patients.

**COMPLICATIONS**
- Complications potentially associated with ACDF include dysphagia, dysphonia, pseudarthrosis, implant failure, neurologic injury, esophageal injury, airway compromise from swelling or hematoma, and vertebral artery injury.
- Some degree of dysphagia is almost universal immediately after surgery. The majority of patients with dysphagia have only mild symptoms, with clinical improvement within 3 weeks. Long-term significant dysphagia is not common (about 4%).
- The superior laryngeal nerve innervates the cricothyroid muscle, which adjusts the tension on the vocal folds and also provides supraglottic sensation. Superior laryngeal nerve palsies therefore may lead to difficulty with singing high notes as well as aspiration.
- The recurrent laryngeal nerve innervates the muscles responsible for abducting the vocal folds. Recurrent laryngeal nerve palsy most commonly presents as hoarseness. Bilateral injuries can lead to airway obstruction and require tracheostomy.
- Even with modern surgical techniques, nonunions still occur. However, many cervical nonunions are asymptomatic and do not require further treatment. Symptomatic nonunions can be addressed with revision ACDF or posterior laminoforaminotomy and fusion.
- It is often argued that fusion accelerates adjacent-segment degeneration. Although biomechanical studies show increased disc pressures and mobility at discs adjacent to fusions, clinical series have not confirmed that adjacent-segment degeneration is truly accelerated by fusion versus simply being a manifestation of the patient’s propensity toward spondylosis. In fact, the available evidence suggests that about 3% of patients will have symptomatic adjacent-segment disease regardless of whether the index operation was ACDF, ACD without fusion, or posterior foraminotomy without fusion.

**REFERENCES**
Cervical myelopathy describes a constellation of signs and symptoms resulting from cervical spinal cord compression. Common symptoms include gait instability, clumsiness and loss of manual dexterity, and glovelike (rather than dermatomal) numbness of the hands. Because the presentation of myelopathy can be subtle, especially in its early manifestation, the diagnosis can be missed or wrongly attributed to “aging.” Surgical decompression is the mainstay of treatment and can be accomplished anteriorly (ie, corpectomy, discectomy and fusion, or both) or posteriorly (ie, laminectomy and fusion or laminoplasty).

Anterior corpectomy and fusion will be discussed in this chapter. Corpectomy is performed when retrovertebral compression of the spinal cord exists. If the compression is purely disc-based, corpectomy is not necessary, and an anterior cervical disectomy and fusion approach can be used instead.

**PATHOGENESIS**

- Spondylotic changes (eg, bone spurs, disc degeneration with annular bulging, disc herniations) are the most common causes of cervical cord compression.
- Ossification of the posterior longitudinal ligament (OPLL) is another not uncommon cause of cord compression. It may arise in discrete locations or be continuous (**FIG 1A,B**).
- Kyphosis, whether primary or occurring after laminectomy, can also cause cord compression and myelopathy.
- Cervical myelopathy often arises in the setting of a congenitally narrowed cervical canal (**FIG 1C,D**). In these patients, the cord may have escaped compression during relative youth but not after the accumulation of a threshold amount of space-occupying spondylotic changes.
- Although cervical spondylotic myelopathy tends to be a disorder seen in patients 50 years of age or older, depending on the degree of congenital stenosis and the magnitude of the accumulated spondylotic changes, it can be seen in patients who are much younger.

**NATURAL HISTORY**

- Patients with cervical myelopathy are generally thought to have a poor prognosis without surgical treatment, with a gradual stepwise progression of symptoms.\(^1\)

**HISTORY AND PHYSICAL FINDINGS**

- Patients with cervical myelopathy present with a spectrum of upper and lower extremity complaints.
- Upper extremity complaints include a generalized feeling of clumsiness of the arms and hands, “dropping things,” inability to manipulate fine objects such as coins or buttons, trouble with handwriting, and diffuse (nondermatomal) numbness.
- Lower extremity complaints include gait instability, a sense of imbalance when walking, and “bumping into walls” when walking. Family members may comment that the patient walks as if he or she is intoxicated.
- Patients with severe spinal cord compression may also complain of Lhermitte symptoms: electric shock-like sensations that radiate down the spine or into the extremities with certain offending positions of the neck (can occur with either flexion or extension).
- Many myelopathic patients deny any loss of motor strength. Similarly, bowel and bladder symptoms, if present, may arise in the later stages of disease. Despite advanced degrees of spondylotic, many myelopathic patients may have no neck pain.
- Symptomatic nerve root compression can coexist in patients with myelopathy and presents as a myeloradiculopathy.

**Physical examination should include:**

- Scapulohumeral reflex testing, which is positive with hyperactive elevation of the scapula or abduction of humerus
- Jaw jerk reflex, which is positive with hyperactive jerking of the jaw. Because cervical cord compression alone will not cause this reflex to be positive, its presence suggests that the origin of upper motor neuron findings in a given patient may arise from the brain rather than the spinal cord.
- Test for spasticity of the great toe, which is positive if the great toe extends while the remaining toes fan apart.
- Test for the Hoffman sign, which is positive with flexion of the index finger and thumb.
- Jaw jerk reflex, which is positive with hyperactive elevation of the jaw. Because cervical cord compression alone will not cause this reflex to be positive, its presence suggests that the origin of upper motor neuron findings in a given patient may arise from the brain rather than the spinal cord.
- Test for the Babinski sign, which is positive if the great toe extends while the remaining toes fan apart.
- Test for the Hoffman sign, which is positive with flexion of the index finger and thumb.
- Jaw jerk reflex, which is positive with hyperactive jerking of the jaw. Because cervical cord compression alone will not cause this reflex to be positive, its presence suggests that the origin of upper motor neuron findings in a given patient may arise from the brain rather than the spinal cord.
- Test for finger escape sign, which is positive if the little finger (also possibly the ring finger) cannot be held in this position without falling into abduction and flexion for more than 30 seconds. This is suggestive of cervical myelopathy.
- Tandem gait test, which is positive if the patient demonstrates significant instability. A positive result confirms gait imbalance, but in no way specifies the source of the imbalance as being the cervical spinal cord.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A lateral radiographic view can be helpful in showing the amount of congenital cervical stenosis as well as sagittal alignment.
- Lateral views are consistent with congenital stenosis when the ratio of the diameter of the canal to the diameter of the vertebral body is less than 0.8.
- Particularly if OPLL is suspected, CT scans (with or without myelograms, depending on whether a high-quality MRI is available) are helpful in delineating bony versus soft tissue pathology.
DIFFERENTIAL DIAGNOSIS

- Of cervical myelopathy:
  - Amyotrophic lateral sclerosis
  - Myopathies
  - Peripheral neuropathy
  - Syringomyelia
  - Multiple sclerosis
  - Diabetic neuropathy
  - Brachial plexopathy

NONOPERATIVE MANAGEMENT

- Surgery is the treatment of choice for symptomatic cervical myelopathy.
- Nonoperative treatment of cervical myelopathy is reserved for patients who cannot tolerate surgery.
- Controversy exists regarding the management of patients with asymptomatic spinal cord compression. In those with severe asymptomatic compression, consideration should be given to prophylactic surgery, particularly if cord signal changes are present, to prevent spinal cord injury with trauma (e.g., central cord syndrome) (FIG 2).

FIG 1 A, B. Ossification of the posterior longitudinal ligament (OPLL). A. Continuous OPLL causing severe spinal canal stenosis from C1 to C4. B. Axial CT scan in a different patient demonstrating a central stalk of OPLL. C, D. Congenital canal. Congenital stenosis is defined as a ratio of the canal to the vertebral body of 0.8 or less, and it can be measured on lateral radiographs (C) or advanced imaging such as CT-myelography (D) (different patients). The CT-myelogram shows superimposed spondylotic changes that further narrow the canal dimensions and cause cord compression.

FIG 2. Sagittal T2-weighted MRI demonstrating spinal cord signal changes.
SURGICAL MANAGEMENT

■ The most common surgical options include anterior decompression and fusion (discectomy versus corpectomy, depending on the absence or presence of retrovertebral cord compression, respectively), laminoplasty, and laminectomy with fusion.

■ In general, anterior surgery is preferred when cord compression arises from three or fewer disc segments, as the incidence of fusion and graft complications increases exponentially with greater number of segments fused. The presence of kyphosis or significant spondyloitic neck pain also favors an anterior approach.

■ Conversely, posterior approaches such as laminoplasty are favored when myelopathy arises from three or more motion segments and the cervical alignment is neutral or lordotic, particularly if the patient has minimal to no neck pain.

■ For posterior surgery to adequately decompress the cord, however, enough lordosis must be present to allow cord driftback after removal of the posterior tethers (lamina, flavum).

■ Combined anterior and posterior surgery should be considered in cases of severe or postlaminectomy kyphosis.

■ Multilevel corpectomy as a stand-alone operation is not recommended in patients with significant postlaminectomy kyphosis, as this creates a highly unstable construct that is prone to failure.

Preoperative Planning

■ Preoperative CT and MRI scans should be scrutinized to analyze the course of the vertebral arteries and the width of the spinal canal requiring decompression.

■ CT scans may provide additional information to MRI scans when it is unclear whether the compressive lesions are bony (OPLL, osteophytes) or soft disc material.

Positioning

■ For anterior cervical corpectomy and fusion, patients are positioned as described in Chapter SP-1.

■ However, greater caution is necessary in positioning the myelopathic versus radiculopathic patient. In particular, one must ensure that the patient is not excessively extended beyond the tolerance of the compressed cord. The amount of extension tolerated preoperatively should be assessed and not exceeded intraoperatively.

■ Gardner-Wells tongs may be used for multilevel corpectomy but are not generally needed for one-level corpectomy.

■ Weight, typically 30 to 40 lb, can be added to the tongs after decompression to allow for distraction during graft insertion. Significant distraction on the spine should be avoided until after the cord has been decompressed.

Approach

■ The approach is similar to that for anterior cervical discectomy and fusion but generally needs to be more extensile to access multiple levels. (Please see Chap. SP-1 for further details.)

■ The surgeon should ensure that wide exposure beyond the medial border of the uncinates is achieved, with appropriate elevation of the longus colli muscles bilaterally, to achieve a stable base for the self-retaining retractors as well as to provide orientation to the uncinates, which remain the critical landmarks for either corpectomy or discectomy surgery.

EVALUATING THE LIMITS FOR THE CORPECTOMY

■ The corpectomy is performed after the initial discectomies above and below the vertebra to be resected. The discectomies are performed from uncinate to uncinate as detailed in Chapter SP-1.1.

■ The width of the corpectomy required to decompress the cord should be based on preoperative imaging studies (TECH FIG 1).
The edges of the corpectomy are longitudinally delineated with a high-speed burr from uncinate to uncinate to define the safe limits of the decompression. Next, a Leksell rongeur can be used to quickly remove large fragments of vertebral body bone (TECH FIG 2). This bone should be saved for grafting. Once the cancellous bone is removed grossly, fine decompression then proceeds with a high-speed burr. Under direct visualization, a high-speed burr is used to remove bone until a thin shell of posterior cortex remains. Microcurettes and Kerrisons are then used to flake off the remaining bone. Attention should be paid to maintaining the width of the corpectomy as it proceeds posteriorly toward the canal, as the tendency is to cone the decompression narrowly as one proceeds posteriorly. Vertebral body bleeding often hinders visualization during bone removal. The surgeon should take time to achieve hemostasis using bone wax (gently applied when the remaining vertebra is still thick) or powdered Gelfoam–thrombin (when the remnant vertebral body is very thin). Significant dorsal pressure should be avoided during these maneuvers to avoid inadvertently plunging into the spinal canal. Epidural bleeding is best controlled with bipolar cautery as well as Gelfoam–thrombin.

**CERVICAL CORPECTOMY**

- Generally, sufficient decompression will occur if the width of the decompression spans from uncinate to uncinate.
- Wider decompressions beyond the medial border to the uncinates are typically performed at the disc level, where a combination of cord and root compression may occur, but are not necessary at the vertebral body level, where only the spinal cord is compressed.
- Staying within the uncinates will allow for thorough decompression while avoiding vertebral artery injury, unless a vertebral artery anomaly exists. Such anomalies are more likely to occur within the vertebral body rather than the disc spaces, and they should be recognized on preoperative imaging to avoid injury.

**TECH FIG 2** • Steps in bone removal. A. Leksell rongeur is used to remove large pieces of vertebral body bone after delineating the lateral edges of the corpectomy longitudinally along the medial border of the uncinates with a high-speed burr. B. After removing the bulk of the vertebra, a burr is used to sequentially remove bone in layers until only a thin remnant of bone remains. C. Finally, curettes and Kerrison rongeurs are used to remove the remaining bone. Adequate thinning of all bone to be removed allows the passage of smaller instruments that do not exert pressure on the spinal cord.

**TECHNIQUES**

**REMOVING THE POSTERIOR LONGITUDINAL LIGAMENT**

- If cord compression arises strictly from bony osteophytes or congenital narrowing of the spinal canal, the PLL does not necessarily need to be resected. In general, we favor removing the PLL to confirm adequate decompression.
- If, however, there is an extruded or sequestered herniated disc behind the vertebral body, or if OPLL is the cause of compression, the PLL should be resected.
- When resecting the PLL, a small curette is used to probe in between longitudinal fibers of the PLL until it can be passed dorsal to it. Once a plane is created, larger curettes or 2- or 3-mm Kerrisons can be used to complete the resection of the PLL (TECH FIG 3).
- If severe OPLL is present, the dura may be deficient or absent, and the surgeon should be prepared to perform a dural patch and possibly a subarachnoid lumbar drain.
- The presence of severe OPLL may favor a posterior approach, all other factors being equal, to avoid complications related to dural deficiencies.
- In severe OPLL, instead of removing the entire OPLL, an alternative technique is to allow it to float anteriorly by releasing its tethers at nonossified portions, then allowing the ossified portion to float anteriorly along with the underlying adherent dura. However, one downside to this approach can be the potential for regrowth of the OPLL.7
TECH FIG 3 • A curette is used to tease apart the longitudinal fibers and create a plane dorsal to the posterior longitudinal ligament (PLL). Once this plane is identified, a curette or pituitary rongeur is used to elevate the PLL while a small Kerrison removes it. The surgeon must be careful never to exert compression on the cord by passing large instruments.

GRAFTING OPTIONS

- Autograft, allograft, or cages can be used.
- Autograft options include structural iliac crest or autologous fibula. Both are excellent graft materials but can be associated with significant donor site morbidity. Because of its shape, iliac crest is generally suitable for one- or sometimes two-segment corpectomy reconstruction. Fibula is favored for two-segment or more corpectomy reconstruction.6
- Because of donor site morbidity issues, allograft fibula or cages filled with local autograft remain popular choices for corpectomy reconstruction.
- Local corpectomy bone can be used to provide the biologic stimulus for healing, allowing the allograft to serve both structural and osteoconductive roles. Local bone is packed in and around the allograft (TECH FIG 4).

TECH FIG 4 • Local morselized autograft is packed around the strut graft and into the cleared-out uncinate regions. An additional benefit of wide discectomy is the ability to fuse the uncinate regions.

ENDPLATE PREPARATION

- The endplates above and below the corpectomy should be thoroughly decorticated and denuded of all cartilaginous material.
- To prevent excessive subsidence, we prefer not to remove as much endplate when performing corpectomy reconstruction as is done when performing anterior cervical discectomy and fusion.
- Nevertheless, it is helpful to remove the anterior lip on the caudal surface of the cephalad vertebra to allow for better contact of the graft to the endplate. The anterior lip is flattened to be level with the central concavity of the endplate (TECH FIG 5A).
- The structural integrity of the endplate is maintained in the central third to allow a stable loading surface for the

Corpectomy autograft

Fibular autograft
If a total corpectomy is performed, care is taken to find a graft that will fill most of the depth of the vertebral body but will still be small enough to stay well clear of the decompressed cord when recessed by 2 to 3 mm from the front of the vertebral body.

If the posterior lip needs to be removed to decompress the cord, it can be done along the floor of the canal with a Kerrison after the corpectomy is completed.

Kickout is most likely to occur at the caudal end of the construct, where the compressive loads on the graft are translated into a shear force due to the relative lordosis of the caudal vertebra. To prevent kickout, the caudal endplate should be prepared parallel to the floor, such that the shear vector is minimized. The tradeoff is that doing so will result in a greater likelihood of subsidence (TECH FIG 5B,C).

GRAFT SIZING

If a total corpectomy is performed, care is taken to find a graft that will fill most of the depth of the vertebral body but will still be small enough to stay well clear of the decompressed cord when recessed by 2 to 3 mm from the front of the vertebral body.

A reasonable amount of distraction should be performed after the decompression. This can be done by the application of weights to cervical tongs or, in one- or some two-level situations, by Caspar pin distraction (the Caspar spreader is usually not long enough to span multilevel corpectomies).

Care should be taken not to distract the spine until all compressive lesions on the cord have been removed, to avoid tenting the cord over the compressive lesions.

In general, the amount of distraction should result in overall vertebral column length that is slightly longer than it was preoperatively. Excessive distraction is more likely to result in subsequent graft pistoning and subsidence, as the spine naturally recoils to its initial state once the patient is upright.

The wooden end of a cotton applicator can be whittled away until it just fits into the corpectomy. This can be used as a template for cutting the graft to appropriate length (TECH FIG 6).

TECH FIG 5 • A. Carpentry of the inferior endplate of the cephalad level: preparing the inferior endplate of the cephalad segment (eg, the inferior endplate of C5 during a C6 corpectomy). Flattening the anterior lip and the anterior third of the endplate allows for proper insertion of a strut graft. They are flattened to be level with the central concavity of the endplate. The central third of the endplate is left as structurally sound as possible to resist excessive subsidence. The posterior third may be left intact to act as a barrier to posterior migration of the graft into the canal. The posterior lip, which is often a source of spondylotic compression, can be removed with a Kerrison after the corpectomy is completed to decompress the floor of the spinal canal. B,C. Carpentry of the superior endplate of the distal level. B. When performing corpectomy reconstructions in which the distal level is lordotic, if the superior endplate of that vertebra is not level with the ground, the graft is likely to kick out anteriorly as the compressive loads on the graft are converted into shear at the graft–endplate interface. C. The solution is to flatten the superior endplate of the caudal vertebra. The graft is now less likely to kick out, but the tradeoff is that it is more likely to piston.

TECH FIG 6 • After applying distraction, a wooden applicator (Q-tip) serves as a useful device for measuring the length of the graft.
**GRAFT INSERTION**

- The graft is gently tamped into the distracted corpectomy site (**TECH FIG 7**).
- Distraction is then released, and the stability of the graft is tested by gently pulling on the graft with a clamp.
- Because bony union is desired not only at the ends of the graft but also side to side between the shaft of the strut graft and the remaining vertebral bodies, intimate contact of graft to host is desirable in all regions. Any open spaces can be grafted with the local bone from the corpectomy.
- If autograft is scarce, it is best to save it for the ends of the allograft strut and fill the middle portion of the marrow cavity with a bone graft substitute.
- The uncinate regions at each disc level are a good surface for fusion and can be grafted with local bone. The residual disc spaces lateral to the medial border of the uncinate can be packed with local bone to facilitate fusion.

**TECH FIG 7** • The graft is inserted under either tong traction or Caspar pin distraction. The superior end of the graft is inserted first, and then the inferior end is gently tamped into position.

**ANTERIOR CERVICAL PLATING**

- Plating is performed as noted during anterior cervical discectomy and fusion.
- Standalone plated multilevel corpectomies (three or more disc levels) have been reported to be associated with high failure rates. Consideration should be given in such cases to supplemental posterior fixation.5

**PEARLS AND PITFALLS**

| Limits of corpectomy | The uncinate should be used as boundaries to prevent injury to the vertebral arteries while achieving wide enough cord decompression. |
| Carpentry of the caudal endplate of the cephalad vertebra | The endplates should be thoroughly decorticated but preserved in the area of contact with the graft to avoid excessive subsidence. |
| Carpentry of the cephalad endplate of the caudal vertebra | If the inferior end of the construct is at a lordotic segment, the endplate should be flattened such that the graft will sit parallel to the ground. Doing so will help avoid kickout. |

**POSTOPERATIVE CARE**

- If retraction time on the soft tissues of the neck has been more than 3 hours, a cuff-leak test should be considered before extubation to rule out the presence of edema that may lead to airway obstruction upon extubation.
- This is performed by deflating the endotracheal tube while obstructing the lumen of the tube, and then determining if there is a leak around the deflated tube. If there is no leak, consideration should be given to keeping the patient intubated with the head elevated until a leak is detected. Steroids can also be given to decrease airway edema.
- The head of the bed should be elevated above 45 degrees in all patients postoperatively to diminish edema.
- Most patients are placed in a rigid cervical orthosis for 6 weeks.
- If a drain is placed, it should be followed closely and removed once the output is below an acceptable limit (ie, 30 cc per shift), typically on postoperative day 1.

**OUTCOMES**

- Although the primary goal of surgery in myelopathy is to prevent progression, most patients actually note neurologic improvement after successful corpectomy and fusion.2

**COMPLICATIONS**

- Complications encountered during the anterior approach to the cervical spine are similar to those discussed in Chapter 11. The incidence of airway obstruction may be higher due to soft tissue edema from longer surgical retraction times.
- Neurologic injury is rare (1% to 2%).
Most complications associated with cervical corpectomies are related to graft and plate problems.  
Dislodgement and pistoning of the graft into the adjacent vertebral bodies with loss of lordosis are potential postoperative complications. The risk increases as the number of levels corpectomized and the length of the strut graft increases. The rate of graft dislodgement ranged from 7% to 50% despite plating in one early series of multilevel corpectomy. To avoid such complications, hybrid corpectomy constructs can be used instead if the pattern of neural compression allows. Hybrid constructs combine corpectomies at levels with retrovertebral compression along with discectomies at levels demonstrating compression only at the level of the disc space (FIG 3).

For a three-disc-level problem, a single-level corpectomy can be combined with a single-level anterior cervical discectomy and fusion.

For a four-disc–level problem, two single-level corpectomies can be performed with an intervening intact vertebra, or a single-level corpectomy with two single-level anterior cervical discectomies and fusions.

Hybrid constructs avoid the negative biomechanical issues associated with long strut grafts and provide more points of segmental screw fixation, leading to constructs that are more stable and less likely to fail. If a posterior approach can be used instead in the patient with multilevel myelopathy, we prefer to do so. Ideal candidates for posterior surgery such as laminoplasty are those with multilevel cervical myelopathy, preserved lordosis, and little to no spondylotic neck pain. In patients like these, fusion and its attendant complications can be avoided altogether with laminoplasty.

Exacerbation of axial neck pain can occur after laminoplasty in those who have significant complaints preoperatively, although it rarely becomes of significance in those who have little to no axial pain preoperatively. Also, adequate decompression may not occur after laminoplasty in those with kyphosis, as cord drift back away from anterior compressive lesions is unreliable in this setting.

REFERENCES

DEFINITION
■ Cervical radiculopathy is a clinical diagnosis defined by the presence of motor or sensory changes or complaints in a specific dermatomal distribution.

ANATOMY
■ Cervical radiculopathy is largely due to mechanical compression of the exiting cervical nerve roots.
■ The intervertebral foramen is bounded by the following structures (FIG 1):
  ▪ The disc and uncovertebral joint ventrally
  ▪ The borders of the pedicles cranially and caudally
  ▪ The superior articular facet of the caudal segment (eg, the superior articular facet of C6 at the C5-6 foramen) dorsally
■ In the subaxial cervical spine, the foramen averages 9 to 12 mm in height and 4 to 6 mm in width, and in a young person, the cervical nerve root occupies approximately one third of the available space in the foramen.
■ With increasing age, degenerative changes (osteophyte formation), disc protrusion, or cervical instability, this proportion may increase and signs of radiculopathy may develop.

PATHOGENESIS
■ Any process that causes impingement of the exiting cervical nerve roots can lead to cervical radiculopathy.
■ Potential etiologies of cervical radiculopathy include cervical spondylosis leading to foraminal stenosis due to uncinate or facet hypertrophy, disc herniation, instability, and anterolisthesis or retrolisthesis.

NATURAL HISTORY
■ The natural history of cervical radiculopathy is not well studied, but about half of the adult population will have neck and radicular symptoms at some point during their lifetime.
■ In patients treated nonoperatively, up to 66% will have persistent symptoms and up to 23% of patients with persistent neck or radicular pain will be unable to return to their original occupation.

PATIENT HISTORY AND PHYSICAL FINDINGS
■ When a patient presents with radiculopathy, a complete history and physical examination is of paramount importance.
■ Questions about the duration of the symptoms, location and nature of the pain, distribution of altered sensation and numbness (axial or radicular), presence of weakness, and any associated manifestations must be asked to understand the underlying pathology and target the offending level of cervical pathology.
■ Since radiculopathy can be associated with myelopathy, the presence or absence of balance difficulties, loss of bowel or bladder control, presence of constitutional symptoms, trauma, signs of dysdiadochokinesia, or change in neurologic status must be elucidated.
■ The physical examination should include motor and sensory evaluation (both gross and pinprick), reflex testing, upper and lower motor neuron signs, and cerebellar functional testing.

IMAGING AND OTHER DIAGNOSTIC STUDIES
■ Plain radiographs of the cervical spine, including anteroposterior (AP), lateral, odontoid, oblique, and lateral flexion/extension views, are used initially to evaluate for the presence of cervical pathology.
■ If symptoms have been present for at least 6 weeks, additional imaging is indicated and usually includes cervical spine MRI.
■ If MRI is contraindicated, a cervical CT myelogram may be beneficial.
■ A CT scan with coronal and sagittal reconstructions may be helpful in operative planning.

DIFFERENTIAL DIAGNOSIS
■ Cervical radiculopathy
■ Myelopathy
■ Myeloradiculopathy
■ Entrapment syndromes (eg, pronator syndrome, carpal tunnel syndrome, cubital tunnel syndrome)
■ Thoracic outlet syndrome

NONOPERATIVE MANAGEMENT
■ Although cervical radiculopathy is common, only a few patients require surgical intervention, and despite a heightened clinical acumen for the diagnosis and treatment of cervical spondylosis, the mainstay of treatment remains nonsurgical.
■ Nonsurgical modalities that are initiated first include physical therapy, nonsteroidal anti-inflammatory drugs, and activity modification.
■ If these methods fail, a selective nerve root injection at a designated level can be attempted with a high degree of safety and efficacy.
■ The purpose of the nerve root injection is twofold: to provide pain relief by decreasing inflammation through the use of a corticosteroid, and to serve as a diagnostic tool to localize the offending pathology.

SURGICAL MANAGEMENT
■ Posterior cervical foraminotomy is indicated for foraminal stenosis or a foraminal disc herniation resulting in a neurologic deficit such as a sensory deficit, motor weakness, and/or progressive symptoms that fail to respond to an appropriate course of nonsurgical treatment.
As with any surgical intervention, a thorough discussion with the patient and family about the desired outcomes and risks and benefits of the procedure must be undertaken before surgery.

**Preoperative Planning**

- To perform an adequate foraminotomy, one must first understand the anatomy of the foramen.
- The basic principle of the procedure is to unroof the foramen, which then allows the nerve root to displace dorsally away from the compressive pathology, which is anterior in most cases.
  - Less commonly, a portion of the superior facet may itself be a source of compression, which can then be directly removed by the posterior foraminotomy.
  - Since the superior articular facet of the caudal cervical segment forms the roof of the foramen, resection of the medial portion of the superior articular facet is necessary to adequately decompress the neuroforamen.
  - Similarly, since the pedicles form the cranial and caudal borders of the neuroforamen, adequate decompression requires resection of the superior articular facet to the lateral margin of the pedicles, as any overhang of the superior articular facet over the caudal pedicle can lead to persistent compression.
  - In contrast, because resection of more than 50% of the facet joint can lead to facet instability, resection of the superior facet lateral to the pedicle is unnecessary.

**Positioning**

- Proper patient positioning is critical when performing posterior cervical foraminotomy to reduce blood loss and improve visualization of the operative field.
- Although there are a variety of ways to position a patient, we routinely place the patient in bivector Gardner-Wells tong traction and position the patient prone on an open Jackson frame (OSI, Orthopaedic Systems, Inc., Union City, CA).
  - This table is quite versatile and allows for intraoperative alterations in patient positioning throughout the operation.
  - Typically, the table is tilted into reverse Trendelenburg to distribute blood into the abdomen and legs, thereby creating a more physiologic state for the patient and providing better visualization in the operative field.
  - To facilitate this position, the head of the table is placed in the top rung and the foot of the bed is placed in the bottom rung.
  - The chest and abdomen are supported on bolsters that allow the abdomen to hang free, and the legs are supported in a sling with pillow support.
  - The shoulders are taped down on both sides to provide traction, thereby allowing better radiographic visualization of the lower cervical spine during intraoperative imaging.
  - Bivector traction is used with the aid of two separate ropes so the neck is maintained in proper alignment, depending on the procedure being performed (FIG 2).
  - One of the ropes is placed in-line and horizontal to the table through a pulley system, and the other is placed over a cross-bar on the Jackson frame to facilitate placement of the head into extension.
  - It is imperative to maintain good coordination and communication with the anesthesia providers during change of positioning of the head, as the endotracheal tube may become dislodged if not secured properly.

**FIG 1** Model showing the posterior element anatomy and boundaries of the foramen.

**FIG 2** Bivector traction technique using the open Jackson frame. Two separate ropes are used so the neck is maintained in proper alignment, depending on the procedure being performed: one of the ropes is placed in-line and horizontal to the table through a pulley system, and the other is placed over a cross-bar on the Jackson frame to facilitate placement of the head into extension. Although not necessary, a horseshoe may be used ventral to the face to catch the head if the tongs slip.
EXPOSURE

- For bilateral foraminotomies, typically a midline incision is used, whereas for a unilateral foraminotomy, an incision approximately 2 cm lateral to the midline can be made (TECH FIG 1A–C).
- With either approach, the lamina, the junction between the lamina and the facet joint, and the facet joint itself have to be exposed while preserving the facet capsule.
- After exposure, the intralaminar V is identified and the decompression is performed (TECH FIG 1D,E).

TECH FIG 1 • A. Dissection of the posterior cervical spine along the midline in the avascular plane. B. Continued dissection, showing midline splitting of the muscles. C. The posterior cervical spine after meticulous dissection of the posterior elements with lateral extension over the facet capsules. Bovie marks illustrate the lateral mass–laminar border. D. Model of the cervical spine showing the C5–6 interspace with the intralaminar V (yellow lines). This is the key anatomic landmark that must be recognized to perform an adequate foraminotomy. E. An intraoperative image showing the C5–6 interspace with the intralaminar V (yellow lines).

- If the neck is not adequately flexed during a foraminotomy, one must resect a large amount of the overhanging inferior articular facet to expose the underlying superior facet.
- This may weaken the lateral mass and lead to a fracture, or more commonly it makes placement of the lateral mass screw more difficult if a fusion is being performed in addition to a foraminotomy.

Approach

- A posterior cervical foraminotomy can be performed using open, endoscopic, or microscopically assisted approaches.
**RESECTION OF INFERIOR ARTICULAR FACET**

- A high-speed 2-mm acorn-shaped carbide-tip cutting burr is used to resect the overlying inferior articular facet and then the medial superior articular facet with the neck in neutral or flexed position (TECH FIG 2).
- Although the inferior articular facet does not cause impingement of the nerve root (the inferior articular facet lies dorsal to the superior articular facet), the overlying inferior articular facet must be resected to the lateral margin of the pedicles to expose the underlying superior articular facet.

**TECH FIG 2**  
A. Model of the cervical spine showing the C5-6 interspace with resection of the inferior facet, which must be resected to the lateral margin of the pedicles to expose the underlying superior articular facet. To determine whether enough of the inferior facet has been resected, a small angled microcurette can be used to palpate the pedicle. B. An intraoperative image showing the C5-6 interspace with resection of the inferior facet. The probe illustrates the cranial extent of the C6 superior articular facet.

**RESECTION OF SUPERIOR ARTICULAR FACET**

- Once the inferior articular facet is resected, the superior articular facet underneath is resected out to the lateral border of the pedicles, completing the decompression (TECH FIG 3).
- During the decompression, copious irrigation (20-mL syringe with a 2-inch-long 18-gauge angiocath) must be used to prevent thermal damage to the surrounding tissues. It also aids in visualization.
- Typically we recommend the use of a burr over Kerrison rongeurs because inserting instruments (such as Kerrison rongeur, which may have a relatively thick footplate) into the already stenotic canal and foramen can cause neurologic damage. However, once most of the roof of the foramen has been removed, it is usually safe to use a 1-mm Kerrison rongeur to clean up any overhanging bone.

**TECH FIG 3**  
A. An intraoperative image showing that once the inferior articular facet is resected, the superior articular facet underneath can be identified. B. The superior articular facet is resected out to the lateral border of the pedicles; this is best performed using an L-shaped resection, as shown in the intraoperative image, to ensure there is no iatrogenic impingement on the nerve root, which can occur if a keyhole or a C-shaped resection of the superior articular facet is performed (see E). C. An intraoperative image showing the completed resection of the superior articular facet. The remaining small ledge of bone can be removed using a small angled microcurette or 1-mm Kerrison rongeur. (continued)
DISCECTOMY

- If the patient has an intraforaminal disc herniation, then the nerve root must be manipulated to expose the herniated disc fragment that is ventral to the nerve root.
- If there is little room for the root to migrate cranially, the cranial 2 to 3 mm of the caudal pedicle may have to be burred down, and a microscopic right-angle probe can then be placed into this space and rotated ventrally to the root to sweep any herniated disc fragment out from under the root, and micro pituitary rongeurs can be used to remove the disc fragment.

CONFIRMATION OF ADEQUATE DECOMPRESSION

- After completing the decompression, a hemostatic agent such as FloSeal or Surgiflo is used to control any bleeding surfaces.
- Once the foraminotomy is completed, the lateral walls of the cranial and caudal pedicles should be readily palpable, and there should be no bone overhanging the medial and superior aspect of the caudal pedicle (TECH FIG 4).

WOUND CLOSURE

- The posterior wound is closed in multiple layers.
- If meticulous midline exposure was performed, the preserved interspinous ligaments with the muscular attachments are used as the first layer of closure. The amount of muscle incorporated into the suture is minimized, since all such muscle will necrose.
- With a well-exposed spine, one can find a thin fascial layer enveloping the muscle that can be used to close the layers.
- The closure progresses from deep to superficial with the placement of deep, middle, and superficial drains.
- The multiple drains prevent isolated pockets of hematoma, which can act as a nidus for infection.
PEARLS AND PITFALLS

Positioning
- Bivector traction with the neck placed in flexion when the foraminotomy is being performed is crucial, as neck flexion unshingles the facets and exposes the underlying superior articular facet.
- Reverse Trendelenburg position helps to decrease blood loss.
- Good coordination and communication with the anesthesia providers during change of positioning of the head is critical.

Exposure
- Meticulous midline dissection through avascular raphe decreases blood loss and allows better closure.
- Care must be taken not to detach the semispinalis cervicis from the spinous process of C2 if a C2-3 foraminotomy is required.
- Care must be taken to remain superficial to the facet capsules during dissection to preserve them, as they provide some protection against postoperative kyphosis.

Decompression
- Adequate decompression requires resection of the superior articular facet (the roof of the foramen) to the lateral margin of the pedicles.
- About 50% (medial-lateral) of the overlying inferior articular facet must be resected to expose the underlying superior articular facet.
- Any overhang of the superior facet over the caudal pedicle can result in persistent nerve root compression.

Closure
- The posterior wound is closed in multiple layers to more closely reapproximate the normal anatomy.

Postoperative course
- Postoperatively, patients do not have any range-of-motion restrictions, nor are they required to wear a brace.

POSTOPERATIVE CARE

- Postoperative pain regimen includes patient-controlled analgesia and ketorolac (Toradol) for 36 to 48 hours in patients under age 65 who have normal renal function and no history of congestive heart failure.
- Patients typically remain in the hospital for 24 to 48 hours, depending on drain output. Patients are discharged on oral pain medication and are instructed to return to the clinic for routine follow-up at 6 weeks postoperatively.
- Although a soft collar is given for comfort, patients are encouraged to discontinue using the collar as soon as they can.
- There are no range-of-motion restrictions, and therapy with immediate motion can begin.
- Rapid return to normal activities and aerobic exercise is encouraged.

OUTCOMES

- Results of posterior cervical foraminotomy are encouraging, with good or excellent outcomes reported in about 90% to 95% of patients.

COMPLICATIONS

- Neurologic injury or worsening radiculopathy
- Infection
- Inadequate decompression or failure to relieve symptoms
- Instability and deformity secondary to overly aggressive decompression
- Air embolism if the procedure is done in a sitting position

REFERENCES

Cervical laminoplasty is a surgical procedure designed to decompress the spinal cord from a posterior approach. The cervical laminae are reconstructed to create more available space for the spinal cord while at the same time preserving motion and normal alignment.

Cervical myelopathy is pathologic spinal cord dysfunction due to spinal cord compression. Compression of neural elements results in a spectrum of cord dysfunction ranging from mild to quite severe. Cervical laminoplasty is most often used to treat cervical myelopathy associated with multilevel cervical stenosis.

Multilevel cord compression is commonly due to cervical spondylotic stenosis. This is a degenerative process resulting in decreased space available for the spinal cord, with possible instability and loss of lordosis. Congenital stenosis of varying degrees is often associated with patients with symptomatic cervical spondylotic myelopathy.

Other conditions such as ossification of the posterior longitudinal ligament, trauma, infection, and neoplasm can result in stenosis that can be treated with laminoplasty.

The key to treating this condition is to achieve multilevel decompression that alleviates circumferential compression and allows the spinal cord to drift away from ventral compressive lesions.

ANATOMY

The cervical spine is composed of seven vertebrae normally arranged in an overall lordotic alignment. The occiput–C1 articulation is responsible for 50% of neck flexion and extension and the C1–C2 atlantoaxial articulation is responsible for 50% of total rotation. Lateral bending below the C2–C3 level is coupled with rotation due to the 45-degree inclination of the cervical facet joints.

The subaxial vertebral segments of C3–C7 are similar to each other and distinct from C1 ( atlas) and C2 (axis). The subaxial vertebrae articulate via zygapophyseal or facet joints posteriorly and laterally via the uncovertebral joints, or joints of Luschka.

Intervertebral discs are located between vertebral bodies of C2–C7. The discs are composed of an inner nucleus pulposus and outer annular fibrosus.

Anteriorly the spinal canal is bounded by the vertebral bodies, the intervertebral discs, and the posterior longitudinal ligaments; laterally and posteriorly by the vertebral arch; and posteriorly by the ligamentum flavum, which runs from the anterior surface of the superior lamina to the posterior surface of the inferior lamina (FIG 1).

PATHOGENESIS

Cervical spondylotic myelopathy is the most common indication for cervical laminoplasty. It is the most common cause of myelopathy in patients older than 50 years. By age 40, most people will have radiographic evidence of degenerative changes.1

The degenerative process typically begins in the intervertebral disc. The degenerated discs are more fibrotic as a result of proteoglycan loss within the nucleus pulposus. This is associated with lost water content from the nucleus pulposus and loss of normal shock-absorbing capacity.

With disc degeneration, the disc height decreases and the annulus fibrosus bulges radially, resulting in ventral spinal canal narrowing. Collapse and loss of lordotic curvature can lead to a cascade of compensatory changes, including osteophyte formation around the uncovertebral joints, the facet joints, and the insertion of the annulus fibrosus. In the dorsal spinal canal, there is thickening or buckling of the ligamentum flavum, which causes a decrease in canal and foraminal dimensions.

Protruded disc material, osteophytes, and thickened soft tissues within the canal or foramen result in extrinsic pressure on the nerve roots or spinal cord. Spondylotic changes and osteophyte compression may also impair the circulation within the cord, leading to cord ischemia and resultant myelopathy.

NATURAL HISTORY

The true natural history of cervical spondylotic myelopathy is difficult to discern. This is due partly to the fact that most cases now are treated surgically and early studies of the disease took place several decades ago. At that time modern diagnostics were unavailable; therefore, confounding variables due to other neurologic conditions cloud the picture.

What is known about the natural history is that the disease process progresses in a variable and unpredictable manner. Often there is stepwise deterioration of neurologic function, with periods of stable symptoms followed by decline.

The clinical course may wax and wane over a period of years. Sensory symptoms may be transient, but motor symptoms tend to persist and progress. While surgical intervention may relieve symptoms and halt progression, some neurologic deficits are permanent and do not respond to surgical treatment.4

PATIENT HISTORY AND PHYSICAL FINDINGS

The diagnosis of cervical myelopathy may be difficult to make due to the variability in clinical findings. Pain is frequently not a significant complaint in myelopathic patients unless associated with root compression or facet arthrosis. Patients may present with subtle findings or profound neurologic deficits.

The diagnosis requires a high index of suspicion and careful evaluation of the patient’s history, physical examination, and imaging studies.
Patients commonly present with insidious onset of gait disturbance, trouble with balance, and clumsiness in the hands and lower extremities. They may report burning pain in the upper extremities, difficulty in handwriting and fine motor control, diffuse numbness, and weakness of grasp. Advanced cases can present with flaccid weakness and bowel and bladder dysfunction.

The physical examination should begin with an assessment of gait, which may be wide-based, hesitant, stiff, or spastic. Patients may be unable to perform heel-toe walk or may have poor balance during toe raises. A careful neurologic examination should follow. Each dermatome should be tested.

Sensory findings may be variable. Pain, temperature, and vibratory and dermatomal sensation may all be decreased.

On the motor examination, depending on the level of cord compression as well as nerve root and peripheral nerve dysfunction, mixed upper and lower motor neuron findings may be present in the extremities. Patients may have weakness and atrophy as well as brisk reflexes.

The Lhermitte sign is said to be positive when extremes of neck flexion or extension result in paresthesias and weakness. This can be a sign of posterior column compression. Pathologic reflexes such as the scapulohumeral reflex (indicates compression above the C3 level), inverted radial reflex (indicates compression at the C5 to C6 levels), the Hoffman sign, clonus, the Babinski sign, and finger escape may be present.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Plain AP and lateral radiographs are useful for initial evaluation of cervical spine sagittal alignment and the extent of spondylotic changes such as disc space narrowing, osteophytes, kyphosis, joint subluxation, and spinal canal stenosis (FIG 2A).

Flexion and extension views can provide information about possible spinal instability.

Magnetic resonance imaging (MRI) aids in determining accurate dimensions of the spinal cord and canal. MRI is also the technique of choice for visualization of soft tissues such as ligamentous hypertrophy, disc herniations, and changes within the cord parenchyma such as edema and myelomalacia (FIG 2B).

Computed tomography (CT) with and without contrast is superior to MRI for defining the bony anatomy and is the
study of choice for evaluating ossification of the posterior longitudinal ligament (FIG 2C,D).

DIFFERENTIAL DIAGNOSIS
- Cervical spondylosis
- Soft disc herniations
- Infectious discitis or epidural abscess
- Muscular dystrophy or dystonia
- Loss of normal sagittal alignment
- Neurogenic disorders (syringomyelia, multiple sclerosis, amyotrophic lateral sclerosis, cerebellar dysfunction)
- Instability of the cervical spine can cause myelopathic symptoms.
- Ossification of the posterior longitudinal ligament
- Peripheral neuropathy or nerve injury
- Drug intoxication
- Vascular disease
- Autoimmune disorders

SURGICAL MANAGEMENT
- Laminoplasty was specifically designed to prevent the kyphotic deformities seen with laminectomy alone and is associated with fewer complications than laminectomy and fusion.²
- Laminoplasty involves posterior decompression from C3 to C7, allowing for dorsal cord expansion and drift while preserving motion.
- Indications
  - Cervical spondylotic myelopathy involving three or more disc levels
  - Congenital stenosis of the spinal canal
  - Ossification of the posterior longitudinal ligament
  - Spinal cord tumors
- Contraindications
  - Kyphotic sagittal alignment of more than 10 to 14 degrees can lead to worsening of the kyphotic deformity and poor neurologic outcomes.
  - Significant segmental instability
- Relative contraindications
  - Ossification of the ligamentum flavum. This condition is associated with dural adhesions, which can make opening the posterior arch difficult.
  - Previous posterior cervical surgery such as foraminotomies. Scar formation can produce adhesions that can make opening the laminar arch difficult.
  - Primary axial neck pain in the setting of myelopathy. Laminoplasty preserves motion, and hence the procedure is not designed to address pain generation from facet arthrosis and disc degeneration. Fusion procedures provide greater benefit to patients with significant complaints of axial neck pain.

Preoperative Planning
- The patient’s history, clinical examination, and imaging studies should be thoroughly reviewed and documented before the case.
- Evaluation of the patient’s active range of motion in flexion and extension assists with head positioning. Passive flexion and extension outside of this range (eg, during positioning) can be dangerous in the setting of cord impingement.
- The presence of preoperative axial neck pain may be an indication for an alternative procedure, as listed above.
- Careful examination of CT scans to determine the bony anatomy of the dorsal cortices can be helpful. Special attention should be given to the lamina-to-lateral-mass junction.
- If concomitant fusion is planned, the midline splitting laminoplasty (“French door”) approach may be considered, but a unilateral open door technique can also be used with fusion and lateral mass instrumentation.

Positioning
- Intubation is preformed with caution to protect the cervical spine. This includes advanced notification to anesthesia personnel of spinal cord compression in severe cases. Care should be taken not to extend the neck more than the patient’s comfortable range of motion before sedation. The use of fiberoptic assistance should be considered in high-risk cases.
- Application of a Mayfield head holder reduces risks to soft tissues and provides a stable platform for the head during the procedure (FIG 3A).
- The patient is placed prone onto chest bolsters. The abdomen should be as free as possible to reduce venous bleeding and prevent ventilatory difficulty. Arms are tucked in at the patient’s side (FIG 3B).
- The head is positioned to allow for slight cervical flexion to tension skin on the posterior neck and decrease shingling (or overlap) of lamina. Intraoperative repositioning of the flexion–extension of the head is possible if necessary with the Mayfield tongs.
- The bed is then placed in reverse Trendelenburg to decrease venous bleeding and allow for horizontal positioning of the cervical spine.
- Spinal cord monitoring is routinely performed in myelopathic patients. This helps to monitor neurologic problems related to positioning as well as with the laminoplasty procedure itself.
- The surgical field should be prepared from the nuchal line to roughly T4 to allow for possible wound extension.

Approach
- A posterior midline incision is made over the spinous processes from C2 to T1. This can be extended to the occiput or further down the thoracic spine as necessary.

FIG 3 • A. The patient’s head is placed in a Mayfield head holder. B. The patient is placed prone onto chest bolsters with arms tucked in at the sides. The head is placed in slight flexion. Spinal cord monitoring equipment is also seen.
INCISION AND DISSECTION

- A posterior midline approach to the spinous processes is made, using a longitudinal incision from C2 to T1.
- Electrocautery is used to divide the subcutaneous fat in the midline to reach the tips of the spinous processes.
- Once the tips of the spinous processes have been found, a subperiosteal dissection is performed to expose the C3–C7 lamina. Careful attention should be taken to stay in the midline avascular plane to reduce bleeding.
  - The dissection should extend laterally to fully expose the junction of the lateral mass and the lamina.
  - Exposure should not extend beyond the midportion of the lateral masses.
- The extensor muscle attachment to the C2 spinous process is carefully preserved. The inferior C2 laminar margin is usually broad and should be exposed to aid in visualization of the C2–3 junction.
- The spinous processes can be amputated at their base. Spinous processes are useful for bone graft (either for strutting open the lamina or for local bone graft for the hinge side).
- Removing the spinous processes significantly improves exposure and reduces asymmetric posterior displacement of paraspinal musculature (TECH FIG 1A).
- The interlaminar ligamentum flavum between C2–3 and C7–T1 is removed. First, a rongeur is used to create a small opening in the interlaminar ligamentum flavum. Then a combination of curette and Kerrison rongeur is used to divide the rest of the interlaminar ligamentum flavum (TECH FIG 1B).

TROUGH PREPARATION

Open-Side Trough

- A 3.0- or 4.0-mm round or oval low-aggression high-speed burr is used to form the trough.
- The trough location is at the junction of the lamina and lateral mass.
- For the opening side, bony layers should be removed in sequence: the outer cortex, next the cancellous middle layer, followed by the ventral cortex (TECH FIG 2A).
- Troughs should be made no deeper than 4 mm. Once at that depth, the burr should be directed medially to avoid the facets. Switching to a 3.0-mm burr can be beneficial after the initial work with the 4.0-mm burr to aid in more precise burring.
- As the bone is thinned, the surgeon should use a delicate instrument such as a microcurette or Penfield elevator to palpate and identify any bone bridges still attaching the lamina to the lateral masses. Completion of the bone separation can be performed with a microcurette, a 1.0-mm Kerrison rongeur, or a diamond burr (TECH FIG 2B).
- Care should be used at this time to avoid the epidural veins, which create significant bleeding. Bipolar electrocautery can be used to control bleeding epidural veins.

French Door (Midline Splitting)

- The French door technique involves creation of a midline opening trough and two hinge troughs.
- The midline of the posterior arch can be split by a variety of methods. One method is to remove the spinous process as described above and use a 4.0-mm low-aggression burr to create a complete midline trough. The burr is carefully manipulated to remove the dorsal midline bone down to the ventral bone (TECH FIG 3).
- Completion of the opening is then performed as described earlier and shown in Techniques Figure 2B.
Hinge-Side Trough

- The hinge side is prepared opposite the opening side at the same anatomic junction of lamina and lateral mass.
- The hinge trough is prepared in a similar manner; however, it entails removal of only the dorsal cortex and cancellous layers. The ventral cortex can be thinned to open the hinge, but the surgeon should preserve as much as possible to preserve a mechanically sound hinge (TECH FIG 4).

- Stiffness of the hinge should be tested periodically during preparation. This is the rationale for performing the hinge after the open side has been completed. The goal is to create a pliable yet firm hinge that yields to moderate opening force without breaking the hinge inner cortex.
- Hinge troughs used for the French door technique are prepared in the same anatomic location as troughs created for the open door technique. Similar to the open door technique, ventral cortex should be preserved to create stable hinges.
OPENING THE LAMINOPLASTY

- Proceeding from caudal to cranial, a nerve hook or curved curette is used to elevate the lamina on the opening side. Division of the residual ligamentum flavum and epidural veins proceeds from C3 to C7. A Kerrison rongeur can be used to divide ligamentous attachments, and bipolar forceps are used for cauterization of epidural veins.
- The laminae are then opened sequentially. This can be done with the assistance of a curved microcurette to raise the opening side and gently bend open each lamina hinge. Care should be taken to identify and lyse any epidural adhesions (TECH FIG 5A).
- Starting from C3 and proceeding to C7 allows for blood to flow away from the working area and reduces the overhang of the inferior edge of the superior lamina due to lamina shingling.
- Completion of opening laminae is carried out carefully with small curettes (TECH FIG 5B).

POSTERIOR ARCH RECONSTRUCTION

- The laminoplasty door is held open using a variety of techniques.
- Plate reconstruction has become popular because of the immediate mechanical security that plates provide (TECH FIG 6A,B). However, eventual mechanical stability relies on hinge-side bony healing to permanently hold the posterior arch open.
- Bone struts can also be used; this was the most frequently used method for many decades. Autogenous spinous process grafts fashioned from the spinous processes of C6 and C7 can be used, as well as rib allograft or machined cortical grafts (TECH FIG 6C).
- Reconstruction with bone has the advantage of allowing for full bony reconstruction of the lamina arch, as the bone struts usually fully incorporate with time. Furthermore, placing bone is easier and faster to place than plate and screws, but bone provides less initial mechanical stability to the arch and may (rarely) dislodge before healing of the hinge.
- Hybrid reconstruction with alternating plate and bone graft can also be used (TECH FIG 6D).
- With the French door technique, midline plates can be applied. Other structures have been used, including autograft, allograft, or hydroxyapatite (TECH FIG 6E).
- Alternatively, the lamina can be held open with sutures that go from the lamina to the lateral mass or facet capsules. Suture anchors have also been used.
Part 9  SPINE • Section II  CERVICAL SPINE SURGERY

WOUND CLOSURE

- A deep drain is placed, followed by a layered fascial and subcutaneous closure.
- Skin is closed using a subcuticular stitch.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Physical examination</th>
<th>The Hoffman reflex can indicate spinal cord compression but can be positive in normal individuals.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Patient position</td>
<td>Slight cervical flexion facilitates exposure and closure by eliminating redundant posterior skin folds and decreases overlap of lamina (laminar shingling) for improved identification of adjacent levels.</td>
</tr>
<tr>
<td>Opening side</td>
<td>If foraminotomies are planned, then the opening side should be made over the ipsilateral side of compression. If asymmetric compression is present, it may be beneficial to open the more affected side. While creating the opening hinge, a color change in the cortex can be appreciated. As the deep (ventral) cortex is thinned, yellow areas (which correspond to ligamentum flavum) and blue areas (which correspond to veins or dura) can be seen through the bone. Care should be taken at this point as the ventral bone is now very thin.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- Typically a soft cervical collar is worn for comfort.
- Most patients can begin immediate active range of motion.
- Drain output is monitored and drains are typically removed by 48 hours after surgery.
- The patient is weaned from the cervical collar over 2 to 4 weeks.

OUTCOMES

- Cervical laminoplasty is a valuable treatment option for myelopathic patients with multilevel stenosis. It provides cord decompression while preserving motion.
- With proper patient selection, neurologic outcomes are excellent, with few complications. In a meta-analysis of results on neurologic improvement, 80% of postoperative patients were reported to have excellent outcomes.²
- When compared with laminectomy with fusion, outcomes regarding neurologic improvement were similar. However, laminectomy with fusion had more frequent complications, such as progression of myelopathy, nonunion, instrumentation failure, development of a significant kyphotic alignment, persistent bone graft harvest site pain, subjacent degeneration requiring reoperation, and deep infection.¹

COMPLICATIONS

- Segmental nerve root palsy: This is most commonly a motor deficit affecting the C5 root that occurs a day or two after surgery. It usually resolves to a large degree with time.
- Axial neck pain has been reported. However, the pain is typically mild and often described as stiffness.
- Loss of cervical motion: Up to 50% loss of range of motion has been reported with some laminoplasty techniques.
- Dural tears are infrequent. They can be handled with either direct repair or with fibrin glue with the addition of a lumbar diverting cerebrospinal fluid drain.
- The infection rate is very low. Good hemostasis and irrigation is recommended.

REFERENCES

Surgical Management

Operative intervention in the posterior subaxial cervical spine is frequently carried out for decompression or stabilization.

Fusion and instrumentation of the posterior cervical spine may be required for unstable fractures or after extensive decompressive procedures.

Instrumentation reduces the need for postoperative immobilization and orthosis wear, augments fusion success, and allows better maintenance of sagittal alignment of the cervical spine.

Interspinous Wiring

Interspinous wiring can be an alternative to lateral mass or pedicle screw fixation in stabilization of the posterior cervical spine.

Although it resists flexion reasonably well, it is generally not as strong in resisting extension, axial load, rotation, and lateral bending.

The most commonly used implants are 18- or 20-gauge stainless steel wire or 1- to 1.2-mm titanium braided cable.

Alternatives include braided stainless steel or polyethylene cable. Multistrand braided steel, titanium, or polyethylene cables show superior fatigue resistance, greater flexibility, and improved stability on flexion-extension testing compared to a single-filament stainless steel wire.

In modern spine surgery, wiring techniques are generally limited to cases in which biomechanically superior techniques such as lateral mass fixation cannot be used, somewhat less invasive midline-only exposure is desired, or the additional rigidity of lateral mass fixation is not necessary (eg, for posterior repair of relatively stable pseudarthroses, or to provide a tension band effect as an adjunct to anterior instrumentation).

Techniques of wiring include simple interspinous wiring (eg, Rogers), Bohlman triple wiring (can be used also for occipitocervical fixation), and oblique wiring.

As a result of the direction of its stabilizing forces, oblique wiring may counter rotational instability better than simple interspinous wiring.

Lateral Mass Screw Fixation

The lateral mass of the subaxial cervical vertebra is a quadrangular column of bone formed by the complex of the superior and inferior articular processes and the intervening bone.

Lateral mass screws are the implants most commonly used at present for posterior fixation of the subaxial cervical spine.

They are versatile in that they can be used when the posterior elements are deficient (eg, from trauma, tumors, or surgical resection for decompression).

Lateral mass screw and rod-plate fixation provides superior flexion and torsional stiffness compared to posterior wiring.

The improved strength of fixation allows instrumentation to be limited to the levels of fusion. When wiring techniques are used, the construct occasionally needs to be extended proximally or distally to obtain additional points of fixation.

A lower incidence of postoperative kyphosis can be achieved with lateral mass screws versus wiring techniques.13

Lateral mass screws have a low incidence of complications and are much easier to insert than cervical pedicle screws.

The Magerl technique of lateral mass screw fixation has been shown to have superior pullout strength and higher load to failure when compared to screws inserted with the Roy-Camille technique.26

This may be related to the longer screw length generally obtained with the Magerl technique (18 mm with Magerl technique versus 14 mm with the Roy-Camille technique).6,16

Pullout strength is significantly greater with a bicortical screw than with a unicortical purchase.

Because bicortical purchase engenders potential risk to nerve roots and the vertebral artery, however, unicortical purchase is used in most cases.

Pedicle Screw Fixation of the Cervical Spine

Pedicle screw fixation allows superior, simultaneous stabilization of all three columns of the cervical spine.

The risk of neurovascular injury from penetration of the small cervical pedicle restricts the widespread use of this technique.

Pedicle screws are most commonly used at C2 and C7, where the pedicles are largest in the cervical spine.

They are often used at the cephalad or caudal ends of long instrumented constructs.

At C7, most patients do not have a vertebral artery in the foramen transversarium, making pedicle screw fixation feasible.

At C2, the vertebral artery is generally lateral to the insertion site and trajectory of the pedicle, making pedicle screw fixation feasible.

From C3 to C6, the proximity of the vertebral artery and the small diameter of the pedicles make pedicle screw fixation challenging and not feasible for routine use.

Whenever pedicle screw fixation in the cervical spine is contemplated, careful scrutiny of preoperative CT and MRI scans is essential.

The cervical pedicle is generally taller than it is wide, with the mean height of all cervical pedicles around 7 mm (range 6 to 11 mm).27

The width of the pedicle is the critical determinant for feasibility of pedicle screw placement.

Pedicle outer diameters less than 4 mm may preclude pedicle screw insertion.12

Multiple morphologic studies have found that the mean cervical pedicle outer width varies from 4 to 7 mm, with significant variation in width at different levels (Table 1).12,24,27
The pedicles of C2 and C7 are generally large enough to accommodate either 3.5- or 4-mm screws. The length of the pedicles from C3 to C6 ranges from 12 to 18 mm. Screw lengths are generally slightly longer to obtain purchase within the vertebral body. The axial angle of the pedicle (medial angle to the sagittal plane) is the least at C2 (25 to 30 degrees) and increases to a mean of 44 degrees (25 to 55 degrees) at C3. From C3 to C7 it gradually reduces to a mean of 37 degrees (33 to 55 degrees).

### POSTERIOR CERVICAL FUSION

- Although it is tempting to focus on instrumentation techniques, performing a meticulous fusion technique is just as important, if not more so, to the success of surgery.
- In virtually all cases, posterior fusion is supplemented by some form of instrumentation.
- To maximize the surface area for fusion, all posterior bony surfaces that do not need to be resected for the decompression should be left intact for fusion.
  - The main priority, however, should always be to first achieve adequate neural decompression.
- After exposure, all soft tissues, including the interspinous ligaments and muscles, facet joint capsules, and paraspinal soft tissue, are meticulously resected so that the cortical surfaces lie exposed.
- Facet joint cartilage is removed with a curette or 3-mm burr within the facet joint.
- The posterior cortical surfaces of the laminae and spinous processes are decorticated with a 3-mm burr to expose bleeding subcortical bone (TECH FIG 1).
- Bone graft obtained from the iliac crest is morselized into small cancellous and corticocancellous chips and on-laid over the bleeding bone.
- Cancellous chips of bone are directly inserted into the facet joint.
- Bone placed between the spinous processes has the additional benefit of being readily visualized on postoperative lateral radiographs obtained to radiographically assess the presence of fusion.

### INTERSPINOUS WIRING

#### Simple Interspinous Wiring

- The spinous processes and laminae at the level to be instrumented should be confirmed to be intact and instrumentable on preoperative imaging studies.
- Closed or operative reduction of spinal fracture-dislocations should be carried out before instrumentation if possible.
- In some cases of flexion–distraction injury, sequential tightening of the wires can be done to reduce the spine.

- Two- to 3-mm drill holes are made through the cortex at the junction of the spinous process and laminae bilaterally, at the levels to be included in the fusion.
- Attention should be paid to the ventral location of the dural sac, and the drill should be directed coronally to minimize the risk of inadvertent spinal cord injury (TECH FIG 2A).
- The drill holes should be positioned at the proximal aspect of the cephalad spinous process and the distal aspect of the caudal spinous process to provide the widest margin of safety against the wire cutting through the spinous process.
The tips of a towel clip or a tenaculum clamp are placed in the cortical holes on either side of the base of the spinous process.
- A gentle side-to-side rocking movement is used to create a continuous tract in the cancellous bone at the base of the spinous process.
- The wire or cable selected for use is passed through and around the base of the cranial spinous process (TECH FIG 2B).
- One end of this wire is similarly passed through and around the base of the caudal spinous process so that both ends of the wire end up on the same side of the spine.
- A plate of corticocancellous bone graft is harvested from the iliac crest and divided into halves.

The graft should be long enough to extend from the superior edge of the cephalad lamina to the inferior edge of the caudal lamina within the fusion levels.
- The cancellous surface of this bone is placed on the decorticated laminae on either side of the spinous process.
- The free ends of the wire are then tightened over the graft (TECH FIG 2C).
- Additional cancellous bone graft is placed over the decorticated laminae and spinous processes and within the facet joint at the fusion levels.

**Triple Wire Technique**
- The wire or cable selected is passed through and around the spinous processes at the cephalad and caudal ends of the fusion levels, as with routine interspinous wiring.

**TECH FIG 2** - Simple interspinous wiring. 
**A.** Safe position of the drill hole for passage of spinous process wire is dorsal to the spinal laminar line. **B.** The wire or cable selected is passed through and around the base of the cranial and caudal spinous processes at the levels selected for fusion, so that both ends of the wire are on the same side of the spine. **C.** Ends of wire are twisted together after releasing any cervical traction.
A pair of corticocancellous plates of bone graft including the full thickness of the cancellous bone of the iliac crest but excluding the inner cortical table is harvested from the posterior iliac crest.

The length of the bone block should be adequate to span the fusion construct and wide enough to cover the decorticated laminae within the fusion levels.

- Two- to 3-mm drill holes are created in the proximal and distal portions of the harvested bone grafts.
- Two additional 22-gauge wires are passed through the holes in the proximal and distal spinous processes.
- These wires are then passed on either side through the holes made in the bone graft.
- The wires are tightened over the grafts on both sides to hold the bone graft rigidly against the decorticated lamina and spinous process (TECH FIG 3).

**Oblique Wiring**

- A periosteal elevator is carefully inserted into the facet joint to slightly distract and clearly identify the plane of the facet joint.
- A 2-mm drill bit is used to make a channel in the sagittal plane through the midportion of the inferior articular process, exiting through the articular surface into the joint.
- The periosteal elevator within the joint confirms penetration by the drill and prevents overpenetration by the drill (TECH FIG 4A).
- A 20-gauge wire or cable is passed through this drill hole and is guided distally through and out of the facet joint using a periosteal elevator in a “shoehorn” fashion.
- One end of the wire is then passed either around or through a hole in the intact spinous process of the vertebra one or two levels caudal to the level of injury.
- This procedure is done bilaterally, and the free ends of the ipsilateral wires are twisted together to the appropriate tension (TECH FIG 4B). The absence of

**TECH FIG 3** Triple wiring technique. After simple interspinous wiring, additional wires are passed through the cranial and caudal spinous processes at the levels selected for fusion. These wires are used to firmly hold corticocancellous plates of bone graft against the decorticated laminae at the fusion levels.

**TECH FIG 4** Facet wiring techniques. A. A channel is drilled in the sagittal plane through the midportion of the inferior articular process, exiting through the articular surface into the joint. A periosteal elevator held within the joint space prevents overpenetration by the drill and can be used to guide the wire out through the joint space. B. Facet wires may be obliquely looped around the spinous process when the lamina is deficient at a level.
laminae or spinous processes is often a reason to consider oblique wiring over interspinous wiring.

- Supplemental midline interspinous or triple wiring is frequently added when the bony anatomy permits.

**Multilevel Buttrress Facet Wiring**

- Posterior stabilization after multilevel laminectomy can also be obtained by posterolateral facet fusion with multilevel facet wiring.8
- Oblique facet wires are passed bilaterally through the inferior articular processes at all facet joints included in the fusion.
  - Two wires are passed through a hole in the spinous process of the most caudal vertebra.
- Rib grafts, iliac crest strut grafts, or metal rods have all been used with the multilevel facet wires (TECH FIG 5).8,14
  - The graft or rod is placed over the decorticated lateral masses and in between the free ends of the wires, and the wires are twisted together at each level to the appropriate tension.

**Postoperative Immobilization**

- Rigid external bracing is recommended in all posterior cervical wiring procedures until solid bony fusion is obtained. Six to 12 weeks of halo vest or rigid cervicothoracic bracing should be used after interspinous or oblique wiring, depending on the stability of the construct and the number of levels included in the fusion.

**LATERAL MASS SCREW FIXATION**

- The quadrilateral posterior surface of the lateral mass is clearly exposed.
  - A ridge between the lamina and lateral mass identifies the medial border.
  - The lateral edge of the lateral mass can be easily palpated.
  - The joint lines above and below delineate the superior and inferior borders.
  - The center of the quadrilateral posterior surface of the lateral mass is identified.
- Several techniques have been described for lateral mass screw insertion.
  - Roy-Camille et al30 proposed an entry point for the lateral mass screw at the center of the posterior surface of the lateral mass.
    - The screw is directed perpendicular to the posterior surface of the lateral mass, angled laterally 10 degrees to the sagittal plane.
    - This trajectory aims to exit lateral to the vertebral artery and inferior to the exiting nerve root (TECH FIG 6A–C).
  - Magerl et al25 proposed an entry point 1 mm medial to the center of the posterior surface of the lateral mass.
    - The screw is directed parallel to the plane of the facet joint with 25 degrees of lateral angulation in the axial plane.
    - This trajectory again aims to exit lateral to the vertebral artery and superior to the exiting nerve root at the junction of the transverse process and the lateral mass.
    - Lining up the screw heads for subsequent fixation to the rod is easier if the most proximal and distal screws are inserted initially, followed by the screws in between.
    - Most current instrumentation systems use a rod to connect the screws after they have been precisely positioned and inserted into the lateral mass.
  - We use lateral-plane fluoroscopy to determine the direction of the screw in the sagittal plane, aiming to keep the screw parallel to and between the articular surfaces of the lateral mass.
  - This trajectory aims to exit lateral to the vertebral artery and superior to the exiting nerve root (TECH FIG 6D,E).
  - A modification of the Magerl et al technique by An et al7 uses a similar starting point but recommends angling the screw 30 degrees laterally in the axial plane and 15 degrees cranially in the sagittal plane.
  - Magerl et al recommended inserting a needle into the facet joint to determine the plane of the joint.
  - Polyaxial screw heads compensate for minor variations in insertion or anatomy.
  - The rods can be contoured in multiple planes and allow for application of compressive, distractive, and rotatory forces for correction of deformity.
  - A rod–screw construct can easily be extended to the occipital and thoracic region.

- Radiographs should show a continuous fusion mass and absence of mobility in flexion and extension before immobilization is discontinued.
Bicortical screws should be considered in certain cases:
- Patients with rheumatoid arthritis or metastatic bone tumors in whom bone quality may be suboptimal.
- Longer fixation constructs extending to the occipital or thoracic regions, to reduce the chances of implant pullout.

## PEDICLE SCREW FIXATION OF THE CERVICAL SPINE

### Insertion of Pedicle Screws from C3 to C7

- Preoperative radiographs and CT images should be reviewed to assess pedicle dimensions and orientation and to confirm the feasibility of obtaining intraoperative radiographs; this is especially important in patients with short, stocky necks.
- Inserting pedicle screws before decompression allows better identification of morphologic landmarks and reduces the risk of inadvertent injury to an exposed spinal cord during the insertion process.
- The most commonly used technique relies on identification of topographic landmarks combined with fluoroscopy.¹
- The entry point to the pedicle is 1 to 2 mm inferior to the caudal edge of the inferior articular process and 2 to...
3 mm lateral to the midline or 2 to 3 mm medial to the lateral edge of the lateral mass.
- Occasionally, degenerative changes at the joint may obscure true landmarks.
- The dorsal cortex of the lateral mass is penetrated using a high-speed burr.
- The cancellous bone of the pedicle in many cases can be visualized in this pilot hole.
- A blunt, fine pedicle probe is advanced through this cancellous bone to find the medially angled pedicle (TECH FIG 7A).
- Fluoroscopy is used to guide the trajectory in the sagittal plane.
- In general, the screws should be parallel to the superior endplate of the vertebral body from C5 to C7 and angled slightly rostral to the endplate from C2 to C4.
- Some authors recommend that a keyhole laminoforaminotomy be performed after locating the entry point.4
- The superior and medial walls of the pedicle are directly palpated through this foraminotomy with a right-angled nerve hook to direct the trajectory of the pedicle probe (TECH FIG 7B).
- The pilot hole is tapped before inserting the screw.
- Size 3.5- or 4-mm screws are generally used, based on preoperative imaging of pedicle dimensions.
- Small pedicle diameters may require a 2.7-mm screw.19
- The length of the screw ranges from 18 to 26 mm, depending on the length of the pedicle as determined on preoperative CT scans.
- The screw should be inserted to a depth no longer than two thirds of the anteroposterior width of the vertebral body, as confirmed on the lateral fluoroscopy image.
- Since the C7 pedicle is longer, a screw up to 30 mm can usually be inserted at this level.

- Computer-assisted image guidance systems have been used for pedicle screw insertion in the cervical spine.
- Preoperative CT data are used by the computer-assisted system to prepare a three-dimensional model of the vertebra.
- After registration of surface landmarks during surgery, a registered probe or drill bit can be used to locate the entry point and guide a fine drill bit through the pedicle into the vertebral body.

C2 Pedicle Screw Insertion
- The entry point for the C2 pedicle is located on the superior medial quadrant of the posterior aspect of the lateral mass of C2, 3 mm lateral to the medial edge of the isthmus, and in line with or slightly distal to the superior margin of the C2 lamina.
- The cortex is penetrated with a 3-mm burr.
- The underlying cancellous bone is probed with a fine curette or pedicle probe to locate the pedicle channel.
- The entry point and trajectory for subsequent drilling are confirmed by palpating the medial and superior margins of the C2 pedicle with a Penfield probe, and with fluoroscopy to determine sagittal angulation.
- The drill is generally angled 15 to 25 degrees medially and 20 to 30 degrees cranially.
- The integrity of the drilled hole is verified with a blunt probe and tapped, and a 3.5- to 4.0-mm screw is inserted.
- Twenty- to 22-mm screw lengths are generally used. C2 pedicle screws longer than 24 mm are likely to penetrate the anterior surface of the vertebral body and may provide superior fixation in some situations.28
- Using a polyaxial screw head allows easier compensation for the difference in medial angulation between the C2 and other subaxial pedicles when connecting to a rod.
Chapter 10  POSTERIOR CERVICAL FUSION WITH INSTRUMENTATION

OUTCOMES

Posterior Wiring Techniques
- Long-term successful fusion rates of 94% to 96% have been reported with interspinous wiring techniques when used for trauma, degenerative conditions, and tumors of the cervical spine.²²,²⁹
- Weiland and McAfee³³ reported a fusion rate of 100% when a triple-wire technique was used for subaxial posterior cervical fusion in 60 patients. Two of the 60 patients required halo vest immobilization, while the rest fused with a two-poster orthosis.
- Cahill et al⁷ reported stable fusion and acceptable alignment in all 18 patients with facet dislocations treated using bilateral oblique wiring. Fusion generally occurred within 3 to 4 months. No patients developed neurologic deterioration after wiring.
- Callahan et al⁸ reported solid fusion in 50 of 52 cases with multilevel facet fusion done after, using iliac crests or rib graft for fixation along with facet wires. Two patients who failed to achieve solid fusion were followed up with regular assessments and did not require any further management.
- Fusion rates with interspinous wiring have been found to be comparable to those obtained from lateral mass plating.²³

Lateral Mass Screw Fixation
- Ebraheim et al¹¹ retrospectively reviewed the radiographic and clinical outcomes in 36 patients treated with lateral mass plate–screw fixation for traumatic instability, post-laminectomy instability, or metastatic disease. Fusion occurred at an average of 3 months in all patients. One patient demonstrated postoperative neurologic deterioration, but this resolved with subsequent decompression.
- Fehlings et al¹³ reported successful arthrodesis in 39 (93%) of 42 patients treated with lateral mass plate–screw fixation for cervical instability at a mean follow-up of 46 months. Revision of posterior plating was required in two patients for a screw pullout. Another patient required supplementary anterior plating for progressive postoperative kyphosis.

Cervical Pedicle Screws
- Screw loosening or pullout has not been an issue with cervical pedicle screw use.
- Abumi et al³ used pedicle screw–rod fixation after correction of cervical kyphosis in 30 patients and reported excellent correction and no adverse mechanical or neurovascular sequelae related to the pedicle screws.

COMPLICATIONS

Wiring
- The most common complication reported with interspinous wiring is loss of reduction and recurrence of the deformity.
- Loss of reduction is more common when posterior wiring is done across a level with fractured posterior elements by bypassing that level.²²
- Osteoporosis or excessive tensioning of the wires may result in intraoperative or postoperative fracture of a spinous process.
- Wire breakage can occur with use of a single-strand wire.
- Use of multistrand cable reduces the risk of wire breakage.¹⁸,³⁴
- Inadvertent passage of spinous process wire through the spinal canal can lead to spinal cord injury.
- Appropriate placement of drill holes at the spinolaminar line and avoiding a ventrally placed tract between the holes on either side should avoid this complication.

Lateral Mass Screw Fixation
- In a cadaveric comparison of different screw placement techniques, Xu et al³⁵ found that violation of either the dorsal or
ventral nerve root was least likely using the modification of the Magerl technique described by An et al. Clinical studies with lateral mass screw insertion have reported a 6% incidence of nerve root injury and a 6% incidence of screw malposition. Three percent of the patients required screw removal for radiculopathy.

Screw loosening is reported to occur with a incidence ranging from 2% to 6%.[1,13,15,17] In addition to direct contact of the nerve root by the screw, radiculopathy can also occur from foraminal stenosis as the lateral mass gets pulled up to the rod during final tightening of the construct. Precise screw length and placement and appropriate contouring of the rod should minimize the incidence of this problem. Vertebral artery injuries have not been reported after lateral mass plating.

Cervical Pedicle Screws

The medial pedicle wall is the thickest, making medial perforation and spinal cord injury less likely. The lateral pedicular wall is thin, increasing the risk of lateral perforation during pedicular screw insertion. There is little to no space between the superior border of the pedicle and the superior nerve root, while there is a mean gap of 1.4 to 1.6 mm between the inferior border of the pedicle and the inferior nerve root.[36] Thus, cortical perforations of the pedicle walls by the pedicular screws are more likely to damage the vertebral artery or superior nerve roots. Abumi et al. reported a 6.7% (45/669 pedicle screws) incidence of cortical perforation by the screw in 180 consecutive patients. Three of the 180 patients developed screw-associated neurovascular complications, with two patients developing radiculopathy that resolved with nonoperative management. One patient developed vertebral artery injury without neurologic sequelae.

Kast et al. reported lateral cortical perforation with more than 25% narrowing of the vertebral artery foramen in 4 of 94 pedicular screws implanted in 26 patients. No vascular or neurologic sequelae occurred with these breaches. Three screws encroached on the intervertebral foramen; one of these screws was revised for a sensory radiculopathy.

Kotani et al. reported reduced pedicle perforation when an image-guided system was used, while other authors have not shown significant improvement in safety or accuracy with these systems.

REFERENCES

DEFINITION

- The term atlantoaxial instability encompasses a number of varied conditions that compromise the normal function of the C1–2 joint, resulting in either pain, spinal cord dysfunction, or the threat thereof.
- Atlantoaxial instability can result from trauma, including rupture of the transverse ligament, odontoid fracture, or Jefferson fracture. Nontraumatic causes include inflammatory arthropathy, osteoarthritis, congenital anomalies, rotatory subluxation, tumor, and infection.
- Several methods have been described for stabilizing the atlantoaxial complex, including wiring techniques, transarticular screw fixation, and, more recently, articular mass screws.
- We describe our technique for transarticular screw fixation and articular mass screw and rod construct to achieve atlantoaxial arthrodesis.

ANATOMY

- The first cervical vertebra, or the atlas, is unlike any other in that it lacks a vertebral body and spinous process. It consists of an anterior and posterior arch connected by two articular masses, forming a ring that pivots about the odontoid process of C-2 (FIG 1A).
- On each side of the cranial surface of the C1 posterior arch there is a groove for the vertebral artery, the first cervical nerve, and their associated venous complex. In a small subset of the population, this groove is covered by an arch of bone, the ponticulus posticus. The resulting foramen is identified as the arcuate foramen
- The articular masses of C1 give rise to the superior and inferior articular facets, which are broad and articulate with the occipital condyles superiorly and the axis inferiorly. A synovial joint also is located between the posterior aspect of C-1 and the odontoid process of the axis.
- The axis (C2) has thicker laminae and a larger bifid spinous process than a typical cervical vertebra. It is characterized further by an odontoid process that projects upward from the vertebral body. Lateral to the odontoid process, or dens, are the sloping superior articular surfaces, which articulate with the inferior articular facets of C1, forming the atlantoaxial joint. The C2 pedicle can be identified in a zone between the lamina and vertebral body, projecting superomedially (FIG 1C,D).
- C1–2 articulation: The C1–2 complex is composed of three articulations, two laterally comprised of the inferior C1 and superior C2 articular facets, and one anteriorly between the dens and the posterior aspect of the anterior C1 arch.
- The C1–2 articulation allows for 47 degrees of rotation to either side, which is approximately 50% of the lateral rotation of the entire cervical spine. Panjabi and associates showed that in the healthy spine C1–2 flexion is 11.5 degrees, extension is 10.9 degrees, lateral bending 6.7 degrees, and axial rotation to each side 38.9 degrees.
- The vertebral artery, which is the first branch of the subclavian artery medial to the anterior scalene muscle, ascends behind the common carotid artery. It then ascends through the foramina transversaria from C6 to C1. After traversing through the foramina transversaria at C1, the artery takes a sharp turn medially and posteriorly to course behind the C1 articular mass along the groove in the posterior arch of C1. It then passes through the posterior atlanto-occipital membrane before ascending through the foramen magnum as it merges with its counterpart to form the basilar artery (FIG 1E,F).
- The C1 nerve root, or the suboccipital nerve, exits cranial to the posterior arch of C1 and innervates muscles of the suboccipital triangle. The C2 nerve root, or greater occipital nerve, exits between the posterior arches of C1 and C2, posterior to the superior C1–2 articulation. It does not exit through a true foramen like the remaining subaxial cervical nerve roots. It traverses inferior to the obliquus capitus inferior to ascend through the semispinalis capitus to lie superficial to the rectus capitis. Injury to the greater occipital nerve can lead to dysesthesia of the posterior scalp and be troublesome to patients.

PATHOGENESIS

- Stability of the C1–2 articulation relies heavily on its ligamentous restraints, including the transverse, alar, and apical ligaments, and the facet capsules. Trauma may disrupt these ligamentous restraints. Also, with the advanced degeneration found in arthritic conditions, these ligamentous structures may become incompetent.
- Up to 3 mm of anterior translation of C1 on C2, as measured by the anterior atlantodental interval (AADI) on a lateral cervical radiograph, is normal. An atlantodental interval of 3.5 to 5 mm in an adult indicates potential damage to the transverse ligament, whereas an interval greater than 5 mm indicates probable injury to the transverse ligament and accessory ligaments.
- In cases of trauma, an atlantodental interval greater than 3.5 mm probably is an indication for further evaluation, and most likely requires C1–2 arthrodesis.
- In patients with inflammatory arthropathy, including rheumatoid arthritis, a canal diameter identified as posterior atlantodental interval (PADI) smaller than 14 mm is associated with a worse outcome and is an indication for decompression and fusion. The exact anterior atlantodental interval measurement is not as relevant in these patients as with trauma patients.
- Fractures that involve the osseous structures of C1 and C2 also may result in atlantoaxial instability and require arthrodesis (FIG 2B).
NATURAL HISTORY

- In the event of C1–2 trauma, the potential need for surgery arises in the setting of ligamentous instability, fractures, or a combination of the two. Atlantoaxial instability due to rupture of the transverse ligament represents a threat to the cervical spinal cord with a low likelihood of successful healing. Thus C1–2 fusion is indicated.
- Transverse ligament disruption in association with a Jefferson fracture may represent an exception to this rule, in that successful nonoperative fracture treatment (halo-vest) can lead to a “stable” C1–2 segment on flexion–extension radiographs.
- Fractures of the odontoid process may represent a primary indication for C1–2 fusion if nonoperative means (eg, halo-vest immobilization) cannot obtain or maintain an appropriate reduction, or if a patient elects surgery to avoid the use of a halo. Displaced odontoid fractures have an increased likelihood of resulting in either non- or malunion in the cases of type II and III fractures, respectively (FIG 3A).
- Primary atlanto-axial osteoarthritis is quite painful and responds poorly to nonoperative means. C1–2 fusion affords a high likelihood of symptom relief (FIG 3B).
- Cervical myelopathy due to either rheumatoid pannus or pseudo-pannus formation, as seen in older individuals with extensive subaxial spondylosis and spontaneous fusion, is unlikely to improve without surgery (FIG 3C).
- C1–2 instability due to rheumatoid arthritis may be neither symptomatic nor a neurologic threat. Thus, in this case, an ADI exceeding 3.5 mm is not, by itself, an indication for surgery. A PADI of less than 14 mm or the presence of myelopathy is a poor prognostic sign and indicates the need
for fusion. Painful C1–2 rheumatoid involvement in the face of adequate medical therapy also indicates the need for fusion. Progressive C1–2 subluxation, especially with cranial settling, also has an unfavorable natural history. C1–2 fusion in this instance will obviate the need for a future occipitocervical fusion, which has a less favorable influence on the overall condition of the cervical spine (FIG 3D,E).

- The natural history of asymptomatic C1–2 instability associated with miscellaneous conditions such as os odontoideum (FIG 3F) and Down syndrome is less clear. When such patients have symptoms, myelopathic signs, or an insufficient PADI, the potential benefits of a C1–2 fusion probably outweigh the risks of the natural history. The patient’s age, lifestyle, and activity level also must be considered in determining the need for surgery.

HISTORY AND PHYSICAL FINDINGS

- A complete history and physical examination, including a thorough neurologic examination, should be performed when evaluating a patient with C1–2 pathology. The complaints offered will vary with the presentation (eg, trauma, inflammatory arthritis, developmental, congenital).

- Patients with a traumatic injury may complain of isolated pain but also may present with neurologic deficits. A low threshold of suspicion should be maintained for patients with blunt trauma to the head or face, or with known noncontiguous fractures of the spine.

FIG 2 • A. An anterior atlantodental interval greater than 5 mm indicates likely injury to the transverse ligament and, in the setting of trauma, necessitates operative stabilization. B. An avulsion (arrow) of the transverse ligament from the ring of C1 indicates instability and may require arthrodesis of C1–2.

FIG 3 • A. Displaced odontoid fractures (type 2) have a higher likelihood of a nonunion and may require a primary C1–2 fusion. B. Joint space narrowing is a sign of C1–2 osteoarthritis and responds poorly to nonoperative management. C. Pseudo-pannus formation behind the dens in patients with rheumatoid arthritis can lead to cervical stenosis and myelopathy. It rarely improves without surgery, but will dissolve after C1–2 fusion. Flexion (D) and extension (E) lateral radiographs demonstrate C1–2 instability in a patient with rheumatoid arthritis. F. Os odontoideum is another condition associated with instability in which part of the dens is not attached to the axis body.
Some patients with rheumatoid arthritis may complain only of axial neck pain, whereas others may present with deteriorating gait and bilateral hand numbness or clumsiness without significant neck pain.

Patients with primary atlantoaxial arthritis will complain of severe neck and head pain, most often unilateral, with varying degrees of refusal to rotate their head, especially ipsilaterally toward the pain. Locking or crepitation of the affected joint may be both audible and palpable.

Physical examination should include the following:
- Active self-limited rotation of the head, especially toward the side of the pain. Normal rotation is up to 50 degrees of rotation to either side. C1–2 pathology often causes pain that limits rotation.
- Palpation of the suboccipital area near the interval between the posterior arches of C1 and C2 will elicit pain. When asked, the patient often can point to the source of their pain.
- Response to traction vs. compression combined with passive C1–2 rotation. The patient is examined supine with his or her head resting comfortably on a pillow. Passive lateral head rotation is measured with slight manual traction. In cases of C1–2 arthritis, this maneuver should provide more motion and less pain than similar motion with an axial vertex load. With slight manual traction, head rotation is increased, whereas an axial vertex load will cause pain and result in decreased rotation.
- In the setting of potential traumatic instability, however, these examination maneuvers are not applicable. The cervical spine must be immobilized until the radiographic and CT findings are known.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- In the setting of blunt trauma, plain radiographs of the cervical spine, specifically the upper cervical spine, have been shown to be inadequate.
  - McCulloch et al\(^{12}\) reported that plain radiographs have a sensitivity of 52%, a specificity of 98%, a positive predictive value (PPV) of 81%, and a negative predictive value (NPV) of 93%, whereas helical CT had a sensitivity and specificity of 98%, PPV of 81%, and NPV of 93%.
  - They concluded that although helical CT has limited ability to detect pure ligamentous injury, it is superior to plain radiographs when evaluating patients with high-energy trauma for cervical spine fractures.
- Other means may be required to evaluate potential ligamentous instability, such as an MRI scan or lateral flexion-extension radiographs under certain circumstances.
- CT with sagittal and coronal reconstruction is done routinely for diagnostic purposes as well as for preoperative planning.
- Fractures of either C1 or C2 indicate a significant likelihood of additional cervical spine fractures. As many as 50% of C1 fractures may be associated with other fractures.
- A vertebral artery angiogram is recommended when there is any question of acute injury or history of injury to the vertebral arteries. A unilateral vertebral artery injury rarely is symptomatic because of sufficient collateral flow through the contralateral vertebral artery as well as the circle of Willis. A patient with a vertebral artery injury who presents with neurologic deficits due to a concomitant spinal cord injury may be especially difficult to diagnose clinically.

We recommend imaging with either an angiogram or an MRA in all patients presenting with a significant flexion-distraction injury, fracture that extends into the transverse foramen, or facet dislocation (FIG 4).
- When discovered, this should be treated with prompt anticoagulation to prevent thromboembolic complications. If a surgical procedure is necessary, anticoagulation is stopped before and restarted after surgery.\(^{3}\)

DIFFERENTIAL DIAGNOSIS
- Rheumatoid arthritis: instability, pannus accumulation, cranial settling.
- Degenerative osteoarthritis
- Trauma: odontoid fracture, Jefferson fracture, transverse ligament rupture
- Tumor
- Infection
- Atlantoaxial rotatory subluxation: recurring subluxation, irreducible and fixed subluxation
- Miscellaneous: Down syndrome, os odontoideum

NONOPERATIVE MANAGEMENT
- In most instances a hard collar is not adequate for immobilizing an unstable C1–2 articulation, but one may be considered in an elderly patient who is not a surgical candidate and otherwise cannot tolerate a halo or Minerva vest (Variteks, Istanbul, Turkey).
- For certain fractures, use of a halo-vest may be appropriate, and the patient is treated in the orthosis for 3 months. It is a time-tested “nonoperative” option with well-defined success/failure rates.
- Some patients may require a halo for postoperative immobilization, depending on the fixation quality, the anticipated level of patient compliance with a hard collar, and other unusual circumstances.

SURGICAL MANAGEMENT
- Several different techniques have been described for successful posterior C1–2 fixation and fusion.
  - Before Jeanneret and Magerl\(^{10}\) described the transarticular screw technique, posterior fixation was accomplished with Gallie’s sublaminar wiring and grafting\(^{6}\) or by the Brooks wiring method.\(^{2}\)
Some of the newer methods include the C1 articular mass and C2 pedicle screw and rod construct described by Goel and Laheri, and the use of a C2 interlaminar screw combined with C1 articular mass screw and rod construct.

Biomechanically, the Magerl technique of transarticular fixation provides the best stability compared with traditional wiring methods, but it may be technically more demanding than either the Brooks or Gallie method of fixation.

Malreduction of C1–2, anomalous position or size of the vertebral arteries, and collapse of the lateral masses of C2 are relative contraindications to the use of the transarticular screw method because of the risk for inadvertent penetration of the vertebral artery.

Preoperative Planning

All imaging studies should be reviewed with regard to osseous anatomy as well as the course of the vertebral artery. Preoperative CT scanning with reconstructed images in the sagittal plane or in the plane of the transarticular screw is necessary to view the pertinent anatomy and to avoid injury to the vertebral artery.

Confirmation of an anatomic reduction of C1–2 intraoperatively is preferable to avoid vertebral artery injury, neurologic injury, and inadequate bony purchase of the screw. However, mild anterior displacement of C1 on C2 is well tolerated and may facilitate fixing the C1 lateral mass, as long as the PADI remains large enough to accommodate the spinal cord.

C1–2 reduction in most trauma conditions can be achieved with longitudinal traction in the awake patient. After successful reduction, a halo vest may be applied to facilitate prone positioning of the patient under anesthesia.

Positioning

The patient is placed in the prone position on bolsters with the head rigidly held in place using Mayfield tongs, or previously placed halo. The shoulders and arms are tucked at the patient’s side.

The table is adjusted into a reverse Trendelenburg orientation, with the knees bent (FIG 5). The shoulders can be depressed with wide tape if necessary to obtain a true lateral view of the C1–2 complex.

After the patient is positioned, the proper alignment of an unstable C1–2 joint should be confirmed radiographically before proceeding further. It is important to confirm that the head is in neutral rotation, to avoid an iatrogenic torticollis.

EXPOSURE

A midline posterior skin and subcutaneous incision is made from the occiput to the spinous process of C7. The deep subperiosteal dissection is confined from the upper edge of C1 to the inferior margin of the C2 laminae (TECH FIG 1).

The longer skin incision permits the correct trajectory of the drill guides, which often are tunneled through the posterior cervical extensor muscles.

A shorter skin incision could be used, with the drills, guides, and other instruments passed through percutaneous stab wounds, but we have found the cosmetic results less desirable.

Muscular infiltration with local anesthetic and epinephrine will reduce bleeding.

MAGERL METHOD OF C1-2 TRANSARTICULAR SCREW FIXATION

Sagittal and axial CT images are scrutinized preoperatively. The isthmus of the C2 pars must measure at least 4.5 mm in height and width to accommodate a transarticular screw. An abnormally large or malpositioned vertebral artery might lead to increased risk of harm to this important structure.

C1–2 reduction and the ability to obtain a true lateral view of C1–2 with a fluoroscope are confirmed.
The starting point for the transarticular screw is at the posterior cortex of the C2 inferior articular process 2 mm cephalad and 2 to 3 mm lateral to the medial border of the C2–3 facet joint.

The starting point is confirmed with a direct lateral C-arm image and marked with a 2-mm burr to provide a secure starting point for the tip of the drill bit. Caudal–cranial angulation is determined via lateral C-arm fluoroscopic guidance. The sagittal plane orientation is confirmed visually with reference to the superior and medial surfaces of the C2 pars. A Penfield 4 dissector can be placed on the dorsal surface of the C2 pars to serve as a guide on the lateral fluoroscopy view.

The K-wire is directed superiorly along the C2 pars while aiming toward the anterior arch of C1 as seen on the lateral fluoroscopic images, with slight medial angulation of 0 to 10 degrees (TECH FIG 2A,B).

We recommend leaving the drill bit or K-wire in place on the initial side to transfix the C1–2 joint, then proceeding to the opposite side. The screw on the second side is inserted before returning to the initial side to remove the drill bit, then tap and insert the second screw. This avoids any problems with loss of reduction (TECH FIG 2C–F).

Bone grafting is performed with autologous iliac crest. After careful decortication of the posterior arches, a modified Gallie technique is employed using either heavy suture or braided titanium cable to secure the graft in place (as described under Gallie Method of Sublaminar Wiring and Grafting).

The extensors at C2 are repaired with drill holes placed through the spinous process.

TECH FIG 2 • A,B. The guidewire is placed superiorly through the pars, aiming toward the anterior arch of C1 on lateral fluoroscopic images. With the first guidewire in place, a second guidewire is placed on the other side. The K-wire is overdrilled with a drill bit (C,D) and tapped, and the screw is placed on the second side (E) before the same is done on the first side. F. Postoperative radiograph of transarticular screw fixation in a patient who sustained a C1–2 fracture-dislocation.

GOEL METHOD OF C1–2 ARTICULAR MASS FIXATION

The ponticulus posticus is a common anomaly that can easily be mistaken for a broad posterior arch of the atlas, and the lateral radiograph must be reviewed to check for the presence of an arcuate foramen to avoid injuring the vertebral artery.17

The starting point for the C1 screw is in the middle of the junction of the C1 posterior arch and the midpoint of the posterior inferior part of the C1 lateral mass. The entry point is marked with a 2-mm high-speed burr.

The C2 nerve root is retracted in a caudal direction for proper screw placement. If divided proximal to the dorsal root ganglia, the patient may experience troubling neuralgia and numbness postoperatively.

The initial drill hole is made in a straight or slightly convergent trajectory in the sagittal plane and parallel to the plane of the C1 posterior arch in the coronal plane, with the tip of the drill aimed toward the anterior arch of C1 (TECH FIG 3A).
The hole is tapped and measured, and a 3.5-mm polyaxial screw of appropriate length is placed so that the screw head stays above the bony surface of the lateral mass to avoid any irritation to the greater occipital nerve.

Care should be taken when dissecting around the C1–2 articulation to avoid excessive bleeding from the epidural venous plexus in this area. Hemostasis can be achieved using bipolar electrocautery, powdered Gelfoam with thrombin, and cotton pledgets.

The center of the lateral mass of C1 is the ideal exit point of the C1 lateral mass screw, and the proximity of the internal carotid artery (ICA) places it in danger when placing a bicortical screw. The ICA can vary in location from side to side and may be within 1 mm of the ideal exit point of a bicortical transarticular screw or a C1 lateral mass screw. Medial angulation of the screw in the lateral mass of C1 may increase the margin of safety for the ICA, but care should be taken to avoid penetrating the occipitocervical joint.

Brooks wiring is the most reliable of the traditional wire fixation methods. It does not provide as much stability as other screw options, however, and so must be used in conjunction with significant postoperative immobilization, often a halo-vest, for optimal likelihood of fusion. It also requires passing sublaminar wires at C2, which can be technically demanding.

Midline posterior subperiosteal exposure of C1 and C2 laminae is carried out with careful attention to dissect from midline laterally at C1 to prevent injury to the vertebral artery. The occipital nerves emerge through the interlaminar space between C1 and C2.

The ligamentum flavum between C1 and the occiput and also between C1 and C2 is sharply divided. A Woodson instrument is used to confirm that there are no dural adhesions in the sublaminar space.

Although Brooks originally described use of two doubled 20-gauge stainless steel wires passed under each side of the arch of C1 followed by C2 with the aid of a no. 2 Mersilene suture in a cephalad-to-caudal direction, we routinely use pairs of braided titanium cables rather than stainless steel wire.

The starting point of the C2 pedicle is in the midline of the C2–3 facet joint, 3 to 5 mm cranial to the C2–C3 articulation. The trajectory is 25 degrees of medial convergence and is aimed 25 degrees cephalad, while keeping in mind that individual anatomy will vary.

A no. 4 Penfield dissector is used to feel the medial border of the C2 pars interarticularis, and the superior and medial aspects of the isthmus are palpated during the drilling process.

The drilled hole is then palpated with a blunt ball-tipped probe. The hole is tapped, and a 3.5-mm polayxial screw is inserted bicortically.

The polyaxial screw heads are connected with two rods. If necessary, a reduction of the C1–2 articulation is performed before fixation with the rods.

The posterior elements of C1 and C2 are decorticated, and a corticocancellous H-graft is secured using a modified Gallie technique (TECH FIG 3B).

The extensors at C2 are repaired using drill holes through the spinous process.
GALLIE METHOD OF SUBLAMINAR WIRING AND GRAFTING

- The Gallie method is less stable than the Brooks method and is relatively contraindicated in the presence of any posterior C1–2 instability. It also requires significant postoperative immobilization.
- The sublaminar cable is passed under the laminae of C1 and C2. We use a suture for this technique when the Gallie graft is employed in conjunction with Magerl transarticular fixation, because the Gallie configuration is relied on for maintenance of graft position, not for mechanical stability.
- A corticocancellous bone graft from the iliac crest (TECH FIG 5A) is taken and placed with the cancellous side facing down on the cortical bone has been burred to reveal a nice bleeding cancellous bed (TECH FIG 5B). The small grooves are placed on the superior and inferior edges of the graft to hold the sutures in place.
- The cable is tightened, and the graft is secured (TECH FIG 5C).

TECH FIG 5 • A. The posterior arches of C1 and C2 are decorticated. B. A corticocancellous graft is taken from the iliac crest. This is fashioned into an H shape, and the cancellous side is placed facing down on the decorticated posterior elements of C1–2. C. A modified Gallie technique is used to secure the graft in place.

PEARLS AND PITFALLS

| Bone grafting | A Gallie H-graft is fashioned from the iliac crest and contoured to fit over the posterior arches of C1 and C2, with its cancellous surface applied directly opposing the decorticated surfaces of C-1 and 2. |
| Frameless stereotactic navigation | This method registers only one vertebra, and the relation of C1 and C2 obtained on the CT scan may differ from that resulting after positioning on the operating table, resulting in aberrant screw placement and possible injury to the vertebral artery, whereas intraoperative fluoroscopy yields real time information. Caution should be used in interpreting the information presented on the 'virtual' images during surgery. |
| Injury to the vertebral artery | Careful preoperative planning will guide selection of the appropriate procedure to reduce the risk of injury. In the event of injury to a vertebral artery during a Magerl procedure, a short screw may be placed to contain the bleeding. If this occurs while drilling or tapping the first side, it is unwise to attempt a C1–2 screw on the contralateral side. An alternative fixation technique should be employed, such as a Brooks or Gallie procedure. |
| Venous bleeding in the C1 lateral mass | Gentle tamponade of the venous sinuses, along with application of hemostatic agents, is recommended. Once the surgical instruments are removed along with the pressure from the retractors, the bleeding is usually is controlled with ease. Avoid indiscriminate use of cautery. |
| Supplemental wire/cable fixation | Supplemental wiring with the Magerl, Goel, and C2 laminar screw methods provides no significant mechanical advantage. However, a suture configuration of a similar nature will hold the graft surfaces in proper apposition to the decorticated host bone, possibly improving the fusion rates. |
| C1–2 facet fusion | Originally described as a component of the Magerl procedure, direct exposure, decortication, and grafting of the posterior aspect of the C1–2 facets is not routinely necessary. It may be indicated for revision procedures, patients with incompetent posterior C–1 arches, or certain fracture patterns, or for high-risk hosts. |
POSTOPERATIVE CARE
- Whereas patients undergoing the Brooks or Gallie procedure obtain a maximal fusion rate with postoperative halo-vest immobilization, the modern screw fixation methods yield fusion rates in excess of 90% with only cervical collars worn for 6–12 weeks.
- The type of collar used and duration of wear should be in accordance with surgeon judgment about host bone, security of fixation, anticipated patient compliance, etc.

OUTCOMES
- Jeanneret and Magerl achieved solid fusion in 13 patients stabilized with the transarticular screw technique.
- McGuire and Harkey showed solid fusion in 8 patients using a transfacet screw technique.
- Fielding and associates achieved fusion in 45 of 46 patients with fractures using the Gallie technique.
- Brooks and Jenkins used a C1–2 sublaminar wiring technique to achieve fusion in 14 out of 15 patients.
- Harms reported fusion in all 37 patients with C1 lateral mass and C2 pedicle minipolyaxial screw and rod construct.
- Cost-effectiveness: The Goel C1–2 articular mass method has been popularized by Harms, and is offered as less risky than the Magerl method with respect to the vertebral artery. However, in the right patient, the Magerl method has proved to be quite safe. The cost of two 4.0-mm cannulated bone screws is substantially less than four polyaxial screws and a pair of rods.

COMPLICATIONS
- Vertebral artery and internal carotid artery injuries
- Infection
- Malpositioned screw
- Nonunion
- C2 neuralgia
- C1–2 hyperextension with Brooks or Gallie procedure if the C1 and C2 arches are compressed together.

REFERENCES
DEFINITION

- Clinically significant lumbar disc herniations are characterized by a focal distortion of the normal anatomic configuration of discal material resulting in compression and subsequent dysfunction of the lumbar nerve roots.

ANATOMY

- The functional components of the intervertebral disc are the annulus fibrosus (fibrous concentric rings, type I collagen) enclosing the central nucleus pulposus (gelatinous, type II collagen, proteoglycans), and the vertebral endplates (hyaline cartilage).
- The anatomic unit of the lumbar spine is the vertebral body with its attached posterior elements and the disc below (FIG 1A).
- The nerve roots travel within the common dural sac (the cauda equina) and then exit at each level. They are numbered according to the pedicle beneath which they pass.
- The spinal canal is divided into zones from medial to lateral: central canal, subarticular zone, foraminal zone, and extraforaminal (far-lateral) zone (FIG 1B).
- Disc herniations are best classified based in the following ways:
  - Based on the integrity of the annulus fibrosus and whether there is a connection of herniated discal material with the disc space (FIG 2)
  - Based on the anatomic location of the herniated material relative to the disc space, the canal, and the compressed nerve root using the nomenclature above (FIG 3)
- Accurate anatomic classification of disc herniations facilitates preoperative planning and can minimize the risk of surgical complications such as missed pathology and iatrogenic nerve root injury.

- The importance of a complete knowledge of spinal anatomy and understanding of the particular patient’s pathoanatomy cannot be overstated.

PATHOGENESIS

- In the normal disc, the nucleus pulposus imbibes and releases water to balance mechanical loads. The annulus fibrosus converts these loads to hoop stresses, thereby containing the nuclear material. The endplates allow diffusion of nutrition into, and waste products out of, the nucleus.
- Together, they allow for the three basic spinal segmental functions: mobility, stability, and protection of the nearby neurologic structures.
- With early or intermediate disc degeneration (natural aging with or without minor repetitive trauma), the endplates fail to allow adequate diffusion, the nucleus fails to replace degraded proteoglycans, and annular support weakens (failure of cross-linking, development of clefts). Biomechanical dysfunction occurs, with possible herniation of nuclear material.
- Many disc herniations do not cause pain or neurologic symptoms. A combination of herniation, nerve root compression, and an inflammatory interface is required for nerve root dysfunction and associated radiculopathy and sciatica.

NATURAL HISTORY

- Many studies have shown that with time and nonoperative treatment, over 90% of patients with a first-time lumbar disc herniation will get better without surgery. Accordingly, to propose surgery requires clear indications.
- Absolute indications
  - Bladder or bowel involvement secondary to a massive disc herniation and cauda equina syndrome: immediate surgical intervention

FIG 1 • A. Anatomic unit. The first floor is the disc level, the second floor is the foraminal level, and the third floor is the pedicle level. B. Regions of the canal.
**Fig 3**. The patterns of disc migration can be characterized relative to the structures of the anatomic unit (e.g., at the disc level or at the pedicle level). The area of root compression can be described relative to the nerve root anatomy (e.g., at the shoulder of the traversing root, in the axilla of the exiting root).

**Differential Diagnosis**

- Intraspinal, extrinsic compression or irritation at the level of the nerve root: spinal stenosis, osteomyelitis or discitis, neoplasm, epidural fibrosis (scar)
- Intraspinal, extrinsic compression or irritation proximal to the nerve root: conus and cauda lesions such as neurofibroma or ependymoma
- Intraspinal, intrinsic nerve root dysfunction: neuropathy (diabetic, idiopathic, alcoholic, iatrogenic [chemotherapy]), herpes zoster, arachnoiditis, nerve root tumor
- Extraspinal sources distal to the nerve root: pelvic or more distal neoplasms with associated sciatic or femoral nerve compression, sacroiliac disease (e.g., infection, osteoarthrosis), osteoarthritis of the hip, peripheral vascular disease

**Nonoperative Management**

- The evidence base is still a bit unclear, but the following are commonly recommended.
- Rest: bed rest (no more than 2 or 3 days), activity or job modification, weight loss
- Medication: analgesics, nonsteroidal anti-inflammatories, tapered doses of oral steroids
- Exercise: physical therapy (McKenzie program)
- Injections: epidural or selective root blocks (may provide some temporary relief while the natural history takes over)
- Time: 6 weeks to 3 months (unless absolute indications for surgery exist as noted above)

**Surgical Management**

- The evidence base is clear: open discectomy and microdiscectomy are the operative techniques with the best-documented long-term outcomes and are the gold standards of surgery for lumbar disc herniations.

**Imaging and Other Diagnostic Studies**

- MRI is the imaging study of choice for the diagnosis and anatomic classification of lumbar disc herniations. It is highly sensitive and specific and provides, along with the clinical picture, adequate information for detailed preoperative planning.

- CT-myelography is invasive and less specific than MRI but provides excellent sensitivity when MRI is unavailable or contraindicated.

- Plain radiographs may show disc space narrowing, early formation of osteophytes, or a “sciatic scoliosis.” While providing no direct evidence of a herniated disc, they may be helpful to rule out unexpected destructive pathology (e.g., infection, tumor, fracture) in patients who have failed to respond to nonoperative intervention or those with red flags. They also allow excellent delineation of bony anomalies that may prove vital to preoperative planning and intraoperative localization, such as transitional lumbosacral articulations or spina bifida occulta.

**History and Physical Findings**

- The most common complaint is pain with or without associated paresthesias or weakness in a specific monoradicular anatomic distribution.

**Classification of Disc Herniations**

- **A** protrusion
- **B** subannular extrusion
- **C** transannular extrusion
- **D** sequestration
The skin incision is made directly midline posteriorly and extends from the top of the cephalad spinous process to the bottom of the caudal spinous process, about 1.5 inches for single-level pathology.

From here, one of two windows of approach will be undertaken based on the location of the disc herniation: the interlaminar window or the intertransverse window.
INTERLAMINAR WINDOW

- The dorsolumbar fascia is incised just off the midline in a gentle curvilinear fashion on the involved side at a length to match the skin incision.
- A Cobb elevator is used to gently elevate the muscle (multifidus) from the spinous processes to the midportion of the facet joint laterally.
  - The degree of muscle elevation should be limited to what is necessary to allow adequate laminar exposure for laminotomy.
- A retractor is then placed. We prefer a retractor with a medial hook for the interspinous ligament and a blade for gentle lateral muscular retraction (TECH FIG 1A).
  - An intraoperative C-arm image is then obtained to confirm the level. Alternatively, a lateral radiograph can be taken.

- A cylindrical retractor, placed transmuscularly using a sequential dilation technique, is a reasonable alternative as long as great care is taken to expose the correct portion of the interlaminar window (there is a tendency to be “pushed” too far laterally).
- At this point, illumination and magnification are gained by the use of the operative microscope (our preference) or a headlamp and loupes.
- Outcomes are similar for the two when used properly, and the surgeon should decide on his or her preference based on experience and comfort level.
- A laminotomy on the undersurface of the cephalad lamina and minimal medial facetectomy is then performed using a Kerrison rongeur (TECH FIG 1B).

**TECH FIG 1 • A. Muscle retractor. B. Laminotomy. C. Laminotomy and the ligamentum. Bony excision used for the “typical disc herniation” in the canal or subarticular zones. It may need to be extended cephalad for herniations extending upward into the second story or may need to include the upper portion of the caudal lamina for herniations extending downward into the third story of the level below. The ligamentum is either freed from its insertions on the undersurface of the lamina above and the undersurface of the facet capsule laterally using a sharp curette, creating a flap, or is incised and split as depicted. D. Identifying the lateral edge of the root. The traversing root is readily identified by vessels that travel along its lateral edge longitudinally, rise up onto its shoulder, and form a plexus in its axilla. Further caudally, the root is closely associated with the medial border of the pedicle.**
The degree of laminotomy and facetectomy should be enough to allow full visualization of the underlying nerve root at the area of compression and to allow access for excision of herniated disc material—no more and no less.

For small disc herniations in the canal or subarticular zones (the “typical disc herniation”), minimal bony excision is required at lower lumbar levels.

For larger disc herniations and those extending cephalad into the second story, a larger laminotomy or even hemilaminectomy may be required. The key in these situations is to preserve at least 5 mm of the lateral pars interarticularis and at least 50% of the medial facet.

Laminotomy of the upper surface of the caudal lamina is generally not needed unless the herniated material has migrated caudally to the third story of the level below adjacent to the pedicle.

The ligamentum flavum is then addressed. One of two techniques is used: the Rick Delamarter and John McCulloch flap or the Rob Fraser split (TECH FIG 1C). The former preserves the ligamentum flavum as a complete barrier to minimize scar formation from posterior, while the latter offers a little less coverage but preserves the ligament’s biomechanical integrity.

The lateral edge of the traversing nerve root is then identified.

This is readily identified by consistent lateral veins and the root’s association with the pedicle (TECH FIG 1D). These veins can then be gently mobilized to allow exposure of the underlying annulus. Occasionally, anomalous roots lateral to the traversing root may be present. Again, safety is ensured by identifying the veins directly overlying the annulus and using these to provide a window to access.

Herniation Exposure

For herniations within the canal or subarticular zones and in the first or second story (85% of encountered discs), the traversing nerve root is gently mobilized medially, allowing exposure of the herniated disc.

If the root is immobile, the surgeon should excise more bone within the subarticular region (medial facetectomy) to afford visualization and palpation of the medial border of the pedicle associated with the traversing root.

Access to the disc cephalad to this will be within a safe zone lateral to the traversing root and within the axilla of the exiting root.

Once larger fragments are teased out, the traversing root will become mobile, allowing greater access.

Retraction should be minimal at upper levels (L1–L3 due to presence of the conus) and limited to about 40%—that is, to less than half the width of the unilateral hemilaminotomy below this (TECH FIG 2).

Retraction should be relaxed during periods in which no active work is undertaken in or near the disc space: the nerve is rested while the pituitary rongeur is being cleaned, and gently re-retracted when it returns. This will minimize trauma to the root.

Hemostasis is then obtained by gently tucking small pieces of Gelfoam or thrombin cephalad and caudally to the exposed disc space. These are to be removed at the end of the case.

If bipolar cautery is used, it should be done with caution to avoid root injury.

Herniations extending caudally to the third story of the level below (uncommon, 5%) are most often within the “axilla” of the traversing root. Retraction of the root is not used; rather, the herniation (usually sequestered) is gently teased out.

Discectomy

Once visualized, any free disc material is removed with a pituitary rongeur. A ball-tipped probe is used to tease out any additional free fragments hiding further out in the subarticular zone or under the common dural sac or root.

The disc space is then entered (this will be the first step in “contained” herniations) by annulotomy. A long-handled no. 15 blade facing away from the traversing root is used, preferably with a longitudinal orientation.

Within the disc space, any loose fragments are removed with the pituitary rongeur (TECH FIG 3), and the disc space is irrigated.

More aggressive excision (“complete discectomy”) may slightly decrease the risk of recurrence, but at the price of increased back pain and a potential for accelerating the degenerative process.

Depth of work should be limited to avoid anterior perforation and potential vascular injury. The surgeon should respect the anterior portion of the annulus and avoid perforating it with an instrument.

Discectomy is complete when no additional loose fragments can be removed from the disc space and free mobility of the nerve root is confirmed.
The root retractor is then removed, along with the pieces of Gelfoam. The wound is thoroughly irrigated. This “washing,” coupled with removing the root retractor, is usually adequate to stop any epidural bleeding. If it persists, temporarily placing Gelfoam again is almost always adequate. Unless there is still a bit of oozing, drains are generally not indicated, and the wound is closed in three layers (fascia, subcutaneous tissue, and skin [absorbable, subcuticular]).

INTERTRANSVERSE WINDOW

- The dorsolumbar fascia is incised 1.5 fingerbreadths off the midline longitudinally (TECH FIG 4A).
- The plane between the multifidus medially and the longissimus laterally is freed by finger dissection, allowing palpation of the facet joint.
- A retractor is placed within this plane (TECH FIG 4B) and an intraoperative C-arm image is obtained to confirm the level.
- The tip of the superior articular process and the lateral pars interarticularis are exposed with electrocautery and partially resected (TECH FIG 4C,D).
- The intertransverse membrane is gently retracted laterally using a ball-tipped probe.
- Gentle blunt dissection is used to identify the exiting nerve root and the underlying herniated material.

Gentle technique, patience, and really good lighting and magnification are required here (again, we prefer the operative microscope, but outcomes are similar regardless). There is plenty of adipose tissue and a venous plexus surrounding the dorsal root ganglion of the root that must be identified before introducing the pituitary rongeur.

- A ball-tipped probe and pituitary rongeur are used to gently tease out the loose fragment, with minimal to no retraction applied to the root. This can be traced back into the disc space as necessary and any loose fragments removed.
- The wound is irrigated, hemostasis is obtained, and closure is performed as described above.

TECH FIG 3 • Discectomy. After annulotomy, the pituitary rongeur is used to remove the herniation and loose fragments within the disc space.

TECH FIG 4 • A. The fascial incision is made 1.5 fingerbreadths from the midline. B. Retraction. (continued)
POSTOPERATIVE CARE

- After surgery, patients may be fitted with a light lumbar corset if desired and are encouraged to walk once anesthesia has worn off and pain permits. About 85% are discharged as outpatients. Fifteen percent will be older (less mobile) or have nausea and vomiting requiring an overnight stay and 23-hour observation.

- Once home, patients engage in a program of progressive walking, stretching, and corset use for comfort. For those progressing slowly, physical therapy may be introduced. Heavy lifting and excessive bending and twisting should be avoided in the first few weeks.

- If all is well, they may drive in about a week and return to light work once they feel up to it. Heavy labor should be avoided for 6 to 12 weeks to ensure proper soft tissue healing (skin, muscle, annulotomy). Long-term activities are not restricted.
OUTCOMES
- There is an 85% likelihood of an excellent or good outcome 5 years postoperatively.
- Patients with significant medical or social comorbidities (eg, diabetes, heavy smoking), worker’s compensation or litigation, and psychological problems (depression) are less likely to do well.
  - Each factor is associated with a 15% reduction in the likelihood of an excellent or good outcome.
- Truly informed consent is recommended.

COMPLICATIONS
- Surgeon-dependent: wrong level, wrong side, missed pathology, iatrogenic instability, “battered root syndrome,” dural tear, hemorrhage, positioning (eg, eyes, ulnar nerve)
- Operative environment or patient-dependent: wound infection, disc space infection, urinary retention, thrombophlebitis or pulmonary embolism

REFERENCES
DEFINITION
- Degenerative changes that are part of the aging process may lead to compression of neurologic tissues within the spinal canal or subarticular zones (with or without the foraminal zone) of the lumbar spine.
- This spinal canal stenosis may lead to neurogenic claudication or a monoradiculopathy.

ANATOMY
- The functional vertebral unit is depicted in FIGURE 1. More details are given in the anatomy section of Chapter SP-12.
- Spinal canal stenosis is best classified based on vertical extent of compression, regions of the canal involved, and severity of the involvement.
- Accurate anatomic classification facilitates preoperative planning and can minimize the risk of surgical complications such as missed pathology and iatrogenic root injury.

PATHOGENESIS
- Degenerative changes can affect the disc, the soft tissues, and the facet joints of the spinal unit.
- Annular bulging of the disc, ligamentum flavum hypertrophy and infolding, and osteophyte formation on the facet joints can contribute to neurologic compression. Occasionally, epidural lipomatosis also contributes to spinal stenosis, especially in the presence of insulin-dependent diabetes mellitus (IDDM).
- This compression occurs slowly and gradually affects the blood supply (arterial inflow and venous outflow) of traversing nerve roots and the free flow of cerebrospinal fluid within the common dural sac. When increased demands are placed, as in walking, the nutritional needs of the nerve roots cannot be met and noxious byproducts of metabolism cannot be removed, resulting in neurophysiologic malfunction characterized clinically by paresthetic and cramping symptoms in the legs.
- As in lumbar disc herniations, many patients with spinal stenosis are asymptomatic, suggesting that other factors intrinsic to nerve root function and adaptability are equally important (eg, smoking, vascular disease, diabetes).

NATURAL HISTORY
- Patients with mild to moderate symptoms and mild to moderate neurologic compression may respond to conservative care. Unless the compression increases, symptoms generally remain stable, with minimal resolution and minimal worsening.
- The more severe the symptoms and the more severe the neurologic compression, the more likely symptoms will progress, the less likely they will respond to conservative measures, and the more likely patients will seek surgical intervention.

HISTORY AND PHYSICAL FINDINGS
- Symptomatic patients with spinal canal stenosis generally present with neurogenic claudication (70%), monoradiculopathy (15%), or a combination of the two.
- Foraminal stenosis (10% to 15% of cases) is best diagnosed clinically by a severe monoradiculopathy of an exiting nerve root, and radiographically on parasagittal MRI imaging or CT sagittal reconstruction (FIG 2).

IMAGING
- As described in Chapter SP-12, MRI is the imaging study of choice for the diagnosis and anatomic classification of spinal canal stenosis.
- CT myelography is invasive and can better resolve the bony component of stenosis compared to MRI. Myelograms taken in flexion-extension may demonstrate a dynamic component to the stenosis. CT myelograms may be particularly useful in patients who have had prior surgery (where MRI may be difficult to interpret due to scarring) and in those with associated spinal deformity (eg, scoliosis).
- Plain radiographs are useful in demonstrating instability in the coronal (lateral listhesis) or sagittal (spondylolisthesis) planes that may need to be addressed with fusion in addition to decompression. Upright anteroposterior, lateral, and flexion-extension views can be obtained.

DIFFERENTIAL DIAGNOSIS
- Vascular claudication, bilateral hip osteoarthritis, peripheral neuropathy, and “pump problems” such as congestive heart failure or coronary artery disease resulting in poor peripheral vascular flow.

NONOPERATIVE MANAGEMENT
- Patients with mild or moderate claudicant symptoms may respond to physical therapy, nonsteroidal anti-inflammatories, and epidural or root sleeve steroid injections. While some patients may relapse into symptoms, many in this group are content to repeat these efforts or to live with their symptoms.
- Patients with significant claudication generally do not respond to nonoperative measures, or they respond only temporarily. Most will elect to undergo operative decompression. Similar to disc herniations, absolute surgical indications include a cauda equina syndrome and progressive neurologic deficits.

SURGICAL MANAGEMENT
- The evidence base is clear: decompressive laminectomy or laminotomy is the operative technique with the best-documented long-term outcomes and is the gold standard of surgery for spinal canal stenosis.
Preoperative Planning
- Planning is vital and should aim to answer several questions:
  - What is the patient’s clinical syndrome?
  - What levels are involved?
  - Is the involvement “intersegmental”?
  - Are the foramina involved?
  - Is there associated pathology: disc herniation, synovial cyst, or degenerative spondylolisthesis or lateral listhesis?
- The answers to these questions will direct the surgical approach, with the goal being complete and safe decompression of compressed neurologic tissue while minimizing damage to tissues not directly involved in the pathologic process.

Positioning
- Prone positioning on a well-padded frame is used (generally the Andrew’s, Wilson, or Jackson; see Fig 4A in SP-12). The hips and knees are gently flexed to decrease lumbar lordosis and to facilitate the interlaminar approach. The abdomen is free to decrease intra-abdominal pressure and venous backflow into the canal.
- Shoulders should be gently flexed and abducted to less than 90 degrees; eyes, elbows, knees, and feet need to be well padded.
- A needle is passed between and lateral to the spinous processes at the involved level or levels and C-arm imaging used to confirm the level. The needle is removed and the level or levels are marked and labeled on the skin (see Fig 4B in SP-12).

Approach
- After initial dissection, one of two windows will be undertaken based on the location of stenosis: the interlaminar window or the intertransverse window.
- The traditional interlaminar approach of laminotomy or laminectomy is used in about 90% of cases of spinal canal stenosis requiring operative intervention.
  - It is used to decompress soft and bony tissues that compress the neurologic structures within the central canal and subarticular zones throughout the lumbar spine.
- Two less invasive approaches may also be used and have outcomes similar to those seen with the more traditional approach: microdecompression via a unilateral approach and microdecompression via spinous process osteotomies.
  - Both techniques afford bilateral decompression of spinal canal stenosis via a unilateral approach.
INCISION

- The skin incision is made directly midline posteriorly and extends from the top of the most cephalad involved spinous process to the bottom of the most caudally involved spinous process (about 1.5 inches for single-level pathology).
- The subcutaneous tissues are gently mobilized and retracted to allow visualization of the dorsolumbar fascia.

Traditional Interlaminar Window for Decompression

- The dorsolumbar fascia is incised in the midline along the length of the skin incision, allowing exposure of spinous processes at each level.
- A Cobb elevator is then used to gently elevate the muscles (multifidus) from the spinous processes and laminae to the midportion of the facet joints bilaterally.
- A retractor is then placed and an intraoperative fluoroscopic image obtained to confirm the levels.
- At this point, illumination or magnification, based upon surgeon preference and experience, is gained by the use of the operative microscope or headlamp or loupes.
- A midline laminotomy is performed on the undersurface of the cephalad lamina to above the level of the insertion of the ligamentum flavum.
  - This laminotomy is then continued into the subarticular zone laterally (medial facetectomy) and then to include the superior surface of the caudal lamina (TECH FIG 1).
  - This bony work allows for exposure and excision of soft and hard tissues compressing the common dural sac and nerve roots and should be enough to get the job done safely and completely while avoiding iatrogenic injury.
- In cases with concomitant congenital stenosis (involvement in the anatomic “third story” [see Chap. SP-12]; about 15% of cases), complete midline laminectomy may be needed because the lamina itself is part of the pathologic compressive process.
  - In the absence of congenital stenosis or deformity, a decompressive procedure that spans the distance from the top to the bottom of the facet joint will adequately decompress the central portion of the canal in most cases. This is because in most cases central stenosis occurs where the disc, ligamentum flavum, and facets converge to impinge upon neural structures.
- Soft and hard compressive tissue is then excised, allowing for decompression of the common dural sac and nerve roots.
  - Generally, no retraction of the underlying dura and roots is needed since most pathology is visible and accessible posteriorly.
  - Concomitant pathology will also need to be addressed if present.
  - Degenerative spondylolisthesis should be treated by spinal fusion with or without instrumentation, as discussed in following chapters.
  - Synovial cysts will need to be completely excised and the pseudocapsule gently peeled from the dura.
  - Disc herniation should be addressed as described in Chapter SP-12.
- The process is repeated at each clinically involved level. Generally, a residual laminar bridge is maintained at each level for routine decompression for degenerative stenosis (laminotomy). Cases of congenital stenosis require midline laminectomy given the compression within the “third story.”
- The wound is then irrigated and hemostasis obtained. The use of a drain is optional, depending on the degree of oozing. The wound is then closed in three layers (fascia, subcutaneous tissue, skin in running subarticular fashion).

TECH FIG 1 • Laminotomy or laminectomy is performed to allow access to the ligamentum flavum, which is excised in its entirety in a trumpeted fashion throughout the segment. Medial facetectomy is included to address any bony stenosis in the subarticular zones.
MICRODECOMPRESSIVE VIA THE INTERLAMINAR WINDOW

Unilateral Approach
- Microdecompression via a unilateral approach may be used for patients with a predominant monoradiculopathy with or without neurogenic claudication and degenerative stenosis with minimal to no spondylolisthesis.
  - In other words, it is a good option in any case that may be adequately decompressed via laminotomy.
  - A unilateral approach and decompression similar to that described above is undertaken on the ipsilateral side.
  - The contralateral side is decompressed via excision of the inferior half of the spinous process and laminar junction, allowing exposure and excision (by working underneath the interspinous ligament) of the contralateral ligamentum flavum via progressive angulation of the microscope, progressive resection of the contralateral laminae (covering the entire area where the ligamentum inserts), and ligamentum resection in its entirety (TECH FIG 2).
  - This operation is technically demanding but affords a recovery similar to that seen with microdiscectomy.

Spinous Process Osteotomy Approach
- Microdecompression via spinous process osteotomies may be used as a less invasive alternative for surgeons more comfortable with the traditional approach.
  - It affords the visualization of traditional midline approaches while preserving the spinous process and interspinous and supraspinous ligaments.
  - A unilateral approach is used, similar to typical discectomy.
  - The spinous processes are then osteotomized just posterior to their junction with the laminae.
  - When the retractor is placed, the typical bilateral interlaminar window is exposed and decompression as described above is undertaken (TECH FIG 3).
  - Once the retractor is removed, the spinous processes fall back into place and generally heal back to the residual laminar ring.

TECH FIG 2 • Microdecompression. A unilateral approach is used and a unilateral decompression performed. The contralateral side is decompressed by angulating under the interspinous ligament in a trumpeted fashion.

TECH FIG 3 • Spinous process osteotomies. A unilateral approach is used and the spinous processes are osteotomized near their base. The spines are then retracted, allowing exposure of the “usual” interlaminar window. After decompression, the spines fall back into place and generally heal to the residual laminar bridge.
Chapter 13 LUMBAR DECOMPRESSION

FORAMINAL DECOMPRESSION VIA THE INTERTRANSVERSE WINDOW

- Foraminal stenosis may be present with or without associated stenosis within the central canal and subarticular zone (addressed separately as above). With the exception of L5–S1, where it is accessible via an interlaminar window, it will need to be addressed via the intertransverse window.
- Adequate decompression of foraminal stenosis via an interlaminar approach requires resection of the lateral pars and results in potential instability at the level. The intertransverse window is a less morbid and easier approach to the foraminal zone and requires minimal resection of the lateral pars.
- The multifidus is taken medially and the longissimus is taken laterally by finger dissection, allowing placement of a retractor in this intermuscular–nervous plane.
- The tip of the superior articular process and the lateral pars interarticularis are exposed with electrocautery.
- Staying within the capsule of the facet joint to protect the underlying exiting root, the surgeon excises the tip of the superior articular process entirely, affording a bony decompression of the foramen (TECH FIG 4). Concomitant soft tissue stenosis (ligamentum flavum insertion in the subarticular zone or lateral disc herniation) can then be easily addressed if present.
- Irrigation, hemostasis, and closure are performed as described above.

TECH FIG 4 • Foraminal decompression. Excision of the tip of the superior articular process and part of the pars interarticularis via a paraspinal approach (A) affords decompression of the exiting root in the foramen (B).

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Wrong-level exposure, exploration, and surgery are always a concern.</th>
<th>The recommendations in Chapter SP-12 discuss how to limit these possibilities.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Revision decompression is difficult due to significant midline scar formation.</td>
<td>The goals should be to find residual lamina and to excise this cephalad and laterally, allowing exposure of previously undisturbed dura and roots. The decompression can then be carried caudally and medially using this normal dura as a guide.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- After surgery, patients are fitted with a light lumbar corset and are encouraged to walk once anesthesia has worn off and pain permits. About 25% will be ready for discharge as 23-hour observation patients. The others (older patients and those with comorbidities) are discharged once they are medically stable and can mobilize adequately.
- Once home, patients engage in a program of progressive walking, stretching, and corset use for comfort. For those progressing slowly, physical therapy may be introduced.
- If all is well, they may drive in about a week and return to light work once they feel up to it. Heavy labor should be avoided for 6 to 12 weeks to ensure proper soft tissue healing. Long-term activities are not restricted.

OUTCOMES

- In most patients, there is an 80% likelihood of an excellent or good outcome 2 years after surgery.
- Patients with significant medical comorbidities (e.g., diabetes, heavy smoking, peripheral vessel disease, coronary artery
disease) are less likely to do well; these comorbidities reduce the likelihood of an excellent or good result by an estimated 15% to 20%.

- Truly informed consent is recommended, as these procedures are not benign in this population.

**COMPLICATIONS**

- Dependent on the surgeon: wrong level, wrong side, missed pathology, iatrogenic instability, root injury, dural tear, hemorrhage, positioning (eg, eyes, ulnar nerve)
- Dependent on the operative environment and patient: wound infection, urinary retention, thrombophlebitis or pulmonary embolism

**REFERENCES**

ANATOMY
- Pedicle morphology is detailed in Table 1.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standing posteroanterior and lateral radiographs should be obtained whenever possible.
- Additional flexion-extension views may provide insight into subtle instabilities (FIG 1).
- Full-length posteroanterior and lateral radiographs are obtained in cases of spinal deformity to assess for global balance (coronal or sagittal).
- Lateral bending views can help determine the flexibility of the curve and levels for fusion.
- Axial computed tomography (CT) images can provide invaluable information about pedicle morphology, particularly in the setting of deformity.

SURGICAL MANAGEMENT
Indications
- Degenerative
- Spondylolisthesis
- Iatrogenic instability
- Discogenic back pain
- Pseudarthroses
- Adult deformity
- Curve progression
- Neurologic deficit
- Back pain refractory to nonoperative care
- Pulmonary compromise secondary to deformity
- Coronal or sagittal imbalance
- Pediatric deformity
- Progressive scoliosis more than 50 degrees
- Kyphosis more than 75 degrees
- Curve progression despite bracing in a skeletally immature individual
- Isthmic spondylolisthesis more than 50%

Preoperative Planning
- Pedicle anatomy can be best assessed on CT (FIG 2).
- A general assessment as to whether a pedicle is instrumentable can be gained by examining its size on an anteroposterior radiograph of the pedicle.
- Pedicle width and length and starting points can be determined from the axial image.

Positioning
- Patients should be placed in the prone position on a radiolucent table (FIG 3).
- Care is taken to ensure that the neck is in a neutral position and is not hyperextended.
- The arms are positioned at 90 degrees or less of abduction to minimize the likelihood of rotator cuff impingement. The arms are allowed to hang down slightly in a forward-flexed position about 10 degrees. The axilla should be clear from any padding to prevent brachial plexus palsy.

- Elbow pads are placed along the medial epicondyle to protect the ulnar nerve.
- The chest pad is placed just proximal to the level of the xiphoid process and distal to the axilla. In women, care is taken to tuck the breasts and ensure that the nipples are pressure-free.
- The iliac pads are placed two fingerbreadths distal to the anterior superior iliac spine, allowing the abdomen to hang free and reducing any unnecessary epidural bleeding.
- Proper placement of the chest and iliac pads allows for optimal restoration of sagittal alignment via gravity.

### Approach

- Two approaches are used: the midline approach and the paraspinal approach.
- The midline approach is used for most spinal procedures as it allows direct access to the spinal canal.
- The paraspinal approach, also known as the Wiltse approach, was initially described for spondylolisthesis but is also used for far-lateral discectomies and minimally invasive muscle-sparing techniques (eg, minimally invasive pedicle screw instrumentation or transforaminal lumbar interbody fusion).
- Specific screw entry points are detailed in Table 2.
Chapter 14  POSTEROLATERAL THORACOLUMBAR FUSION WITH INSTRUMENTATION 4611

THORACOLUMBAR PEDICLE SCREW PLACEMENT

Pedicle Start Point

- Once the bony anatomy of the dorsal elements is meticulously exposed, the proper position of the pedicle entry point is defined. Anatomic landmarks include the lateral edge of the facet joint, the pars interarticularis, and the transverse processes (TECH FIG 1A).
- The actual pedicle starting point may vary significantly from the commonly quoted “norms” in many patients. What follows are general guidelines. Preoperative imaging studies (such as CT scan, or even the relationship between the pedicle and the lateral aspect of the pars on an anteroposterior radiograph) can provide clues about anatomic variations in a given patient or level.
- In both the lower (T10–12) and upper (T1–3) thoracic spine, the entry point is at the junction of the bisected transverse process and the lateral edge of the pars interarticularis.
  - In the midthoracic region (T5–9), the starting point is more medial and cephalad. Here, it is at the junction of the superior margin of the transverse process and the lateral third of the superior articular process (TECH FIG 1B).
- In the lumbar spine, the entry point is at the midpoint of the transverse process and 2 mm lateral to the pars interarticularis.
  - The sacral entry point is at the inferolateral aspect of the L5–S1 facet joint.
  - Using a 4-mm high-speed burr, the posterior cortex is breached to a depth of about 5 mm (TECH FIG 1C).
  - Alternatively, the “bull’s-eye” technique with fluoroscopy can be used to correctly identify the starting point, particularly when patient anatomy is distorted (TECH FIG 1D).

Cannulating the Pedicle

- A 3.2-mm hand drill is placed into the starting hole and advanced along the axis of the pedicle (TECH FIG 2A,B).

The drill is advanced under fluoroscopic guidance into the vertebral body to an ultimate depth of 35 to 40 mm in the lumbosacral spine, 25 to 30 mm in the lower and upper thoracic spine, and 30 to 35 mm in the midthoracic spine.

- Measurements of pedicle length can be made on axial CT or MRI scans and used to guide screw length.
- The advantage of using a hand drill is that cortical violations are lessened. When resistance is met (cortex), the drill fails to advance, and consequently the angle is adjusted.
- Alternatively, a “gearshift” type of device can be used to sound the pedicle. The gearshift should be rotated or wiggled as it is advanced with only gentle pressure. This technique allows the instrument to seek the proper path within cancellous bone rather than being pushed forcefully through a cortical wall. The process is analogous to feeding a guidewire into a vein during central line placement: the idea is to provide guidance, not force, to the instrument as it navigates a path within the cortical margins of the bone.
- For the S1 pedicle, the drill is directed 25 degrees medially and 10 degrees inferiorly toward the sacral promontory. A lateral fluoroscopic image is used to identify the sacral promontory (TECH FIG 2C).
- Ideally, the screw tip should achieve tricortical purchase (engaging the anterior and posterior cortex and superior endplate of S1) (TECH FIG 2D).
- A flexible ball-tipped probe is then advanced down the pedicle tract. Bone should be encountered at the base of the tract as well as along all four walls of the pedicle.
- Medial and lateral cortical breaching is most common as the pedicle is narrowest in this plane.
- A medial pedicle breach is most likely to occur at a depth between 15 and 20 mm ventral to the transverse process, which is the depth at which the spinal canal is encountered in most levels.
If a proper start site is selected, lateral breaches are more likely to occur deeper than 20 mm due to failure to medialize and follow the proper trajectory as the pedicle transitions into the vertebral body. However, if the start site is too lateral, a lateral breach may occur more superficially.

Pedicle Screw Sizing

- With the ball-tipped probe advanced along the length of the pedicle tract, the surgeon measures the tract depth using a hemostat and a ruler (TECH FIG 3A).
- In general, pedicles are tapped 1 mm smaller than the diameter of the screw to be used to optimize screw purchase. If the pedicle is sclerotic, "line-to-line" tapping should be performed. If the patient is osteoporotic, tapping is not necessary.
- After tapping, the ball-tipped probe is again advanced through the pedicle tract to confirm that the pedicle cortices and anterior vertebral body are intact.

- A Kirschner wire is then placed into the pedicle while the remaining pedicle tracts are cannulated.
- All Kirschner wires are confirmed to be positioned properly via fluoroscopy. At this point, fusion bed preparation may occur (TECH FIG 3B,C).

Fusion Bed Preparation

- The wound is copiously irrigated before decortication to preserve the local bone graft generated with high-speed burring.
- Using a high-speed burr, the transverse process, the pars interarticularis, and the lateral wall of the facet joint of each level to be fused are decorticated.
- Bone graft is placed over the decorticated areas. The fusion bed can be prepared with any combination of autogenous iliac crest bone graft, autogenous local bone graft (from the spinous processes and lamina), allograft, demineralized bone matrix, or bone morphogenic protein (TECH FIG 4).
PELVIC FIXATION

- Sacropelvic fixation can be used in the setting of long-deformity reconstructions and tumor and in traumatic settings involving the lower lumbosacral spine.
- Modern pelvic fixation is most easily accomplished via modular iliac screw placement.
- After dissection of the posterior superior iliac spine, a starting point is identified 1.5 cm distal to the tubercle.
- A burr or rongeur is used to create a recessed defect such that the iliac screw head will lie recessed within the posterior superior iliac spine.
- A gearshift is then inserted into the starting point and advanced between the inner and outer tables of the pelvis, with the medial point of the probe scraping along the medial wall.
  - The trajectory should generally aim toward the hip joint.
  - The cortex of the medial wall is thicker than the lateral, and thus lateral violations are more likely than medial violations.
- A ball-tipped probe is used to assess the inner and outer tables.
- Depth is measured and the screw is inserted. The screw is typically 7.5 to 8.5 mm in diameter and roughly 60 to 80 mm long (TECH FIG 5).

CROSS-CONNECTORS

- Cross-connectors can significantly increase the rotational and bending stiffness of a multilevel construct.
- One, two, or three cross-links can be used, depending on the length of the construct. If multiple cross-connectors are used, they should be spread as far apart as possible from each other for maximal construct rigidity.

HOOK INSERTION

- Hooks can be placed about the pedicle, transverse process, or lamina.
- Fixation is increased with a claw configuration.
- A claw configuration is composed of two hooks directed toward each other, separated by one or two levels. Claws are primarily used at the ends of a construct (TECH FIG 6A).
- Pedicle hooks provide the strongest fixation of all hook constructs. Always oriented cephalad, the pedicle hook is placed between the lamina of the superior vertebra and the superior articular process of the inferior vertebra (TECH FIG 6B). The U-shaped tip fits around the pedicle and allows for increased stability.
- The inferior facet of the vertebra can be removed with an osteotome. It is helpful to resect enough of the facet so that the lateral edge of the spinal canal is identified so that it can be avoided during implant placement. The cartilage of the superior facet is removed with a curette. A pedicle hook developer is

TECH FIG 4 • After decortication, bone graft is placed over the decorticated areas.

**PEARLS AND PITFALLS**

- Careful assessment of preoperative imaging (CT) allows for more accurate pedicle screw placement.
- Breaching the medial or inferior pedicle cortex endangers the exiting nerve root. Medial pedicle breaches are typically identified at a depth of 15 to 20 mm.
- Fluoroscopy can be used to identify proper pedicle starting points when patient anatomy is distorted.
- Too medial a starting point for pedicle screw entry may injure the supra-adjacent facet joint.

**POSTOPERATIVE CARE**

- With secure multilevel pedicle screw fixation, it is probably not necessary to brace patients postoperatively, although that decision should be individualized based on the patient’s pathology.

**COMPLICATIONS**

- Infection
  - The incidence of infection for posterior spine surgery is increased with the addition of an instrumented fusion.
  - A 1% infection rate has been noted for discectomies, a 6% infection rate for discectomies and fusion.
Although there is a wide range reported for instrumented posterior fusions, the overall infection rate appears to be around 5% to 6%.

Pseudarthrosis (nonunion rates, particularly crossing the lumbosacral junction)

- The incidence of nonunion after posterior lateral intertransverse fusion ranges from 3% to 25%.
- Smoking has been shown to be a risk factor for nonunion.
- A wide range of fusion rates across the lumbosacral junction has been reported (22% to 89%).
- A 92.5% fusion rate is reported across the L5–S1 junction when using iliac screws.

Neurologic and vascular injury

- Although there is potential for severe vascular injury with pedicle screws in the thoracolumbar spine, vascular complications are rare, outside of a few reports.
- The risk of nerve root irritation has been reported to be very low (0.2%) from pedicle screw instrumentation.

REFERENCES

Several types of lumbar arthrodesis have been developed to address the various pathologic processes that occur.
Each of these fusion techniques offers certain advantages and disadvantages that provide the surgeon with a range of options for addressing each patient’s condition.

The standard lumbar arthrodesis techniques include:
- Anterior lumbar interbody fusion (ALIF)
- Posterior spinal fusion (PSF), which includes two subtypes: posterior interlaminar and facet fusion
- Posterior lateral intertransverse fusion
- Combined anterior and posterior fusion (AP fusion or 360-degree fusion)
- Posterior lumbar interbody fusion (PLIF) and its variant the transforaminal lumbar interbody fusion (TLIF)
- The PLIF procedure uses a posterior approach to the spine that involves radical discectomy and endplate preparation combined with an interbody fusion using a structural graft or cage with or without supplemental posterior instrumentation.
- The TLIF procedure is similar to PLIF with the modification that the interbody region is accessed unilaterally via a more lateral approach in conjunction with pedicle screw instrumentation.
- PLIF and TLIF are versatile techniques that offer several advantages over the other fusion methods.
  - They allow for pathology in all three columns of the spine to be addressed and for a circumferential fusion to be achieved through a single posterior approach.
  - They directly address the disc as a potential pain generator in patients with discogenic pain syndromes.
  - They have demonstrated a high rate of fusion that approximates the arthrodesis rate achieved with a more extensive combined anterior and posterior fusion procedure.
  - They allow for direct decompression of the spinal canal if necessary.
  - They permit some correction of spinal deformities, including asymmetric disc space collapse, spondylolisthesis, and mild kyphosis.
- PLIF and TLIF procedures also avoid some of the drawbacks inherent to anterior lumbar interbody fusion procedures, such as:
  - There is a reduced risk of the complications associated with an anterior approach, including vascular injury, higher rates of thromboembolic disease, and retrograde ejaculation in males.
  - They preserve a virgin anterior approach should revision surgery become necessary or should an adjacent segment arthroplasty become an option in the future.
- PLIF and TLIF have the disadvantage, however, of potential nerve root injury from preparation and instrumentation of the disc space through a posterior approach.

The major difference is that the PLIF procedure uses a bilateral and more-medial approach to access the interbody region, whereas the TLIF technique involves a unilateral approach with complete removal of one facet joint to allow more lateral access to the disc space (FIG 1).
- As a result, the exiting root is in greater danger when performing a TLIF, whereas the traversing root is in greater danger with a PLIF.
- Gaining access to the posterior annulus and interbody region during TLIF and PLIF procedures is a critical step that requires an understanding of the local neurologic anatomy and the triangular working window to the annulus. The triangular working window consists of the following:
  - The traversing nerve root and thecal sac form the medial border of the triangle.
  - The exiting nerve root from the proximal vertebral level forms the lateral border (eg, L4 for an L4–5 TLIF or PLIF).
  - The superior aspect of the pedicle of the distal vertebra forms the base of the triangle.
  - A confluence of epidural veins traveling longitudinally and transversely drapes the floor of the spinal canal and neuroforamen.
  - With careful exposure, a triangular working window measuring up to 1.5 cm wide and of slightly greater height can be created.
  - A noncollapsed disc space of an adult lumbar spine averages between 12 and 14 mm in height, with an anteroposterior diameter of about 35 mm.

The PLIF and TLIF procedures allow for fusion of the anterior column of the spine in the interbody region, which offers several biologic and biomechanical advantages over posterior spinal fusions:
- The anterior column of the spine is known to support 80% of the body’s compressive load; consequently, intervertebral structural grafts are subjected to compressive loading, which facilitates arthrodesis.
- Since interbody structural grafts are load-sharing, they significantly reduce the cantilever bending forces applied to posterior spinal implants, thus protecting them from failure.
- The interbody space has been shown to provide an optimal milieu for promoting arthrodesis for several reasons:
  - A large surface area of highly vascular cancellous bone is available.
The disc space represents a relatively shorter gap to span when compared to intertransverse fusion.

The outer annulus serves as a barrier that reduces fibrous tissue ingrowth into the fusion mass during healing of an interbody arthrodesis.

**INDICATIONS**

- Discogenic pain syndromes due to internal disc disruption or degeneration as well as postdiscectomy chronic low back pain are well suited to PLIF or TLIF for several reasons:
  - These procedures directly address the disc as the pain generator and have been shown to have superior clinical outcomes in treating discogenic pain compared to isolated posterior spinal fusions, which do not remove and fuse the painful disc.
  - They allow for restoration of interbody height and some correction of local kyphosis without putting undue stress on the posterior implants.
  - They permit decompression of the exiting and traversing nerve roots indirectly by restoring foraminal height and directly via open laminectomy and foraminotomy. Because of this, PLIF and TLIF are ideally suited to patients with discogenic pain syndromes occurring in conjunction with radicular symptoms caused by herniated disc pathology or stenosis (FIG 2).
  - Low-grade isthmic spondylolisthesis can also be treated successfully with PLIF and TLIF procedures as an alternative to performing a combined anterior and posterior fusion. PLIF and TLIF allow for direct decompression of the spinal canal and exiting nerve roots as well as indirect foraminal decompression through restoration of disc space height.
  - Addition of the interbody fusion raises the arthrodesis rate over stand-alone posterior fusion.
  - When clinically indicated and with proper instrumentation, PLIF and TLIF allow for reduction of the spondylolisthesis and slip angle, with some restoration of lordosis. In experienced hands and in conjunction with a wide decompression and intraoperative neurologic monitoring, some higher-grade spondylolistheses can be successfully reduced and stabilized with the PLIF and TLIF procedures.
  - PLIF and TLIF procedures can be a useful adjunct to adult deformity surgeries such as degenerative scoliosis and spondylolisthesis and offer several advantages:
    - They can be used to provide anterior column support at the caudal end of fusion constructs and the lumbosacral junction without requiring an additional anterior approach to the spine.
    - They improve the arthrodesis rate, which can be helpful when an interlaminar fusion is not possible because a midline decompression was necessary to address spinal stenosis.
They allow for some additional deformity correction by releasing asymmetrically collapsed disc spaces and providing interbody structural support.

Several recent presentations (not yet published) have found that routine cases of degenerative spondylolisthesis may not benefit from the addition of an interbody arthrodesis and may be best managed with standard posterior laminectomy and fusion procedures.

PLIF and TLIF can also help raise the fusion rate in arthrodesis procedures in which clinical conditions pose a challenge to spinal fusion, such as:

- Patients unwilling or unable to quit smoking
- Patients with diabetes mellitus or on systemic corticosteroids
- Patients on chemotherapy or with an irradiated fusion bed
- Revision spinal fusion procedures in which the posterolateral fusion bed is fibrotic and hypovascular
- Any other situations in which the clinician feels that the addition of an interbody arthrodesis is justified because conditions exist that may impede the formation of a posterior arthrodesis

**CONTRAINDICATIONS**

- PLIF should not usually be attempted at the level of the conus medullaris (typically L1–2) or above, and great caution must be taken using the TLIF procedure at the level of the cord or conus.
- Severe osteoporosis is a relative contraindication to these procedures as disc space preparation can result in major endplate violations with subsequent implant subsidence.
- Anomalous neural anatomy such as a conjoined nerve root can make the performance of a PLIF or TLIF procedure impossible.
- Even in some cases of “normal” nerve root anatomy, local variations in take-off angles of the exiting and traversing roots can place the roots at risk during interbody approaches. Caution should be exercised in such cases and interbody fusion abandoned if not felt to be safe.
- Severe focal kyphosis is poorly addressed with a PLIF or TLIF procedure and is usually better treated with an anterior procedure that allows for release of the anterior longitudinal ligament and annulus fibrosus.
- Irreducible higher-grade spondylolisthesis are not well treated with the PLIF and TLIF procedures as the surface area of the opposing vertebral endplates is minimized.

**NONOPERATIVE MANAGEMENT**

- Before considering PLIF and TLIF surgeries, standard nonoperative management options for the pathologic conditions being addressed should typically be exhausted.
- Nonsurgical treatment usually involves a combination of analgesic medications, physical therapy, and activity and lifestyle modification. When applicable, interventional pain management techniques such as trigger point injections, facet blocks, or epidural steroid injections should be considered.
- Surgical intervention is usually reserved for patients who remain symptomatic despite several months of nonoperative treatment and whose symptoms are severe enough to justify the risks associated with operative care.

**SURGICAL MANAGEMENT**

- As mentioned earlier, PLIF and TLIF procedures are capable of addressing a wide variety of pathologic conditions and in specific situations offer several compelling advantages.
- Given their versatility, the well-trained spinal surgeon needs to be aware of the indications for these procedures and must be capable of executing them properly.
- While the usefulness of the PLIF and TLIF procedures is clear, one must remain mindful that these procedures are technically demanding and should be undertaken only after careful training and preoperative planning and with meticulous surgical technique.

**Preoperative Planning**

- Preoperative imaging studies should be reviewed to determine the appropriate size and trajectories necessary for pedicle screw insertion as well as the anteroposterior diameter of the disc space.
- Disc space height as well as adjacent disc height and overall lumbar alignment should be measured to help determine optimal interbody implant size.
- An assessment should be made as to whether direct or indirect neurologic decompression will be necessary.
- When using the TLIF technique, the interbody approach should be performed on the patient’s symptomatic side if he or she has radicular complaints or from the side of maximal neurologic compression if the lower extremity symptoms are of equal severity.
- Although sometimes difficult to assess, the patient’s MRI needs to be studied carefully to identify anomalous neural anatomy such as a conjoined nerve root.
- If a conjoined nerve root is suspected, the TLIF should be performed from the opposite side and the patient should be counseled preoperatively that the interbody portion of the procedure may not be possible because the contralateral side may demonstrate intraoperative nerve root anomalies as well.
- For the PLIF procedure, the presence of a conjoined nerve root usually necessitates a unilateral PLIF. If identified preoperatively, conversion to a TLIF should be strongly considered.
- Deformity at the level of the planned fusion needs to be assessed so that intraoperative measures can be taken to provide for correction.

**Positioning**

- The patient should be positioned prone on an operating room table that allows for fluoroscopic imaging, such as a Jackson spine table (FIG 3).
- The abdomen should be free to decompress the vena cava. This maneuver has been found to reduce epidural venous engorgement and bleeding.
- A Foley catheter and lower extremity sequential compression devices should be used routinely.

**FIG 3** • Prone positioning with the abdomen free of compression, lower extremity compression devices in place, knees flexed, and all bony prominences padded. All tubes and wires are secured so that the area under the patient is free of obstruction, which facilitates later use of the fluoroscopy unit.
Distraction option 1: Use of rods and screws

Several methods of achieving interbody distraction exist, after screw placement, the next step is to provide posterior distraction to open the posterior portion of the disc space.

- Lumbar disc spaces are normally lordotic, which can make insertion of an appropriate-sized interbody cage through the narrow posterior portion of the disc space difficult.
- With distraction, the disc space alignment can be neutralized, thereby facilitating access to the interbody region with minimal bony resection.
- Several methods of achieving interbody distraction exist, and these can be combined as needed to achieve the desired alignment. The choice of distraction technique is largely based on surgeon preference, as all three methods have been found to be effective.

- Distraction option 1: Use of rods and screws
  - Rods are loaded bilaterally into the pedicle screws, followed by provisional placement of the system’s locking nuts.

- Distraction option 2: Spinous process distraction
  - Distracting off the spinous process can reduce the risk of screw loosening that might occur with excessive distraction on the pedicle screws.

- Distraction option 3: Interbody dilators
  - Another option available to facilitate interbody distraction is to use interbody dilators, which are placed into the disc space and rotated to restore disc space height (TECH FIG 1E).

This technique minimizes stress applied to the posterior implants and provides the most powerful method of vertebral body distraction.

**Approach**

The standard posterior approach to the lumbar spine is used, including exposure out to the tips of the transverse processes so that an adequate intertransverse fusion can be performed.

- Some surgeons choose to perform a more limited dissection and do not perform the posterolateral portion of the fusion, hoping that by preserving the blood supply and muscular attachments in the intertransverse region there will be reduced erector muscle dysfunction and fibrosis with improved outcomes.

**Disc Space Distraction**

- After screw placement, the next step is to provide posterior distraction to open the posterior portion of the disc space.
- True minimally invasive TLIF options have been developed. With these techniques, the procedure is modified so that it can be carried out through cannulas and with percutaneous instrumentations. These modifications will not be discussed in this chapter. The surgeon should be adept at open interbody fusions before considering minimally invasive approaches.
- For the standard TLIF procedure, the spinous processes and interspinous ligaments can usually be left intact. Preserving these structures minimizes epidural scarring and provides a larger surface area for the posterior fusion.
- If decompression of the contralateral side of the spinal canal is required, the TLIF procedure can be modified to include a central laminectomy.
- Two exposure options exist for the PLIF procedure, each of which will be discussed in more detail later in the chapter:
  - Extensive resection including wide laminectomy with bilateral facetectomies
  - Limited resection using bilateral laminotomies and medial facetectomies

**Pedicle Screw Insertion**

- After exposure, pedicle entry points are identified at the junction of the transverse process with the superior articular process of each vertebra.
- A high-speed burr or awl is then used to access each pedicle, followed by use of a pedicle probe and tap to create a proper path for the screws.
- Polyaxial pedicle screws are then placed bilaterally in the standard fashion.
- Fluoroscopy or image guidance systems, electromyographic responses, or both can be used to aid in proper screw positioning.
- If desired, the transverse processes can be decorticated using a high-speed burr or curette before screw insertion. This is recommended to facilitate the posterior arthrodesis as access to the transverse processes becomes somewhat limited once the pedicle screws are in place.

**Transforaminal Lumbar Interbody Fusion**

- Distraction is then carried out using the rods on both sides and a standard distractor (TECH FIG 1A–C).
- To allow for the distraction, the rods need to be slightly longer than will ultimately be necessary.
- The polyaxial screw heads should be angled as laterally as possible to maximize the volume of space medial to the rods. This maneuver facilitates later access to the disc space without requiring rod removal.
- Alternatively, several systems have pedicle screw distractor instruments that provide distraction off the screws without requiring rods to be inserted.
- Distraction instruments obviate the need to use longer rods and allow for unimpeded access to the facet and disc space during interbody preparation and implant insertion.
- Lateral fluoroscopy should be used to judge the amount of distraction obtained at the posterior margin of the disc space.
- Once adequate alignment is obtained, the system’s locking nuts are tightened to maintain the distraction.
- Care should be taken not to excessively distract off the screws in osteoporotic patients, as this could lead to screw loosening.

- Distraction option 2: Spinous process distraction
- Distraction can also be achieved by using a lamina spreader placed between the spinous processes (TECH FIG 1D).
- Distracting off the spinous process can reduce the risk of screw loosening that might occur with excessive distraction on the pedicle screws.

- Distraction option 3: Interbody dilators
- Another option available to facilitate interbody distraction is to use interbody dilators, which are placed into the disc space and rotated to restore disc space height (TECH FIG 1E).

This technique minimizes stress applied to the posterior implants and provides the most powerful method of vertebral body distraction.
Use of interbody distractors is not possible until access to the disc space has been achieved, so this technique is not an option until the disc space has been accessed.

**Complete Unilateral Facetectomy**

- The inferior articular process of the cephalad vertebra should be exposed and removed using an osteotome or rongeurs (TECH FIG 2A).
- The superior articular process of the caudal vertebra is then dissected free of the ligamentum flavum with curettes and removed using Kerrison rongeurs. To maximize access to the disc space, the entire superior articular process down to the cephalad aspect of the pedicle should be removed so that the top of the pedicle can be easily seen and palpated (TECH FIG 2B).
- The lateral aspect of the hemilamina and the caudal portion of the pars interarticularis are resected using Kerrison rongeurs to provide access to the neural foramen and posterolateral annulus.
- The triangular working zone between the exiting and traversing nerve roots and the superior aspect of the pedicle should be identified (TECH FIG 2C).
  - The exiting nerve root is present just below the pedicle of the cephalad vertebra.
  - The exiting nerve can be identified visually or palpated but should not be deliberately manipulated as the sensitive dorsal root ganglion is in this region.
  - While it is critical to identify the location of the exiting nerve root, care should be taken not to unnecessarily dissect the nerve out of its sleeve of fatty tissue; in some cases the nerve will be located and palpated but never fully visualized.
- The traversing nerve root and the lateral aspect of the thecal sac will be present in the medial portion of the triangle. Nerve root retractors can be used to mobilize the neurologic elements medially to provide additional access to the posterolateral annulus (TECH FIG 2D).
- As in all lumbar spinal surgical procedures, if trouble is encountered locating a nerve root, the surgeon should find or palpate the associated pedicle and look along the medial and inferior pedicle wall.
- With the neurologic elements accounted for, the posterolateral annulus can be accessed through the previously described triangular working zone by carefully coagulating and dividing the obstructing epidural veins using bipolar cautery (TECH FIG 2E).
- Significant bleeding can be encountered at this stage, and the use of cottonoids in conjunction with hemostatic agents such as Gelfoam, Floseal, or Surgiflo can be helpful.
- If the surgeon is not careful, the exiting or traversing nerve roots can be damaged while dealing with the bleeding arising from the epidural venous plexus. Working methodically while remaining constantly aware of the location of these neural structures is critical.

**Disc Space Preparation**

- A nerve root retractor is used to mobilize the thecal sac and traversing nerve root medially to improve exposure
of the posterolateral annulus. An advantage of the TLIF procedure is that minimal neural retraction is necessary to access the interbody region. Depending on the local nerve root anatomy, however, retraction of the traversing root may be necessary even with a TLIF.

- A scalpel is then used to incise a rectangular region of the annulus lateral to the traversing nerve root to create a window into the disc space (TECH FIG 3A).

- It is extremely important to have proper instruments available to facilitate the critical step of disc space preparation. These instruments are frequently provided by the vendor of the graft or implants to be used in the interbody region and should include (TECH FIG 3B):
  - Interbody paddle scrapers to dilate and prepare the endplates
  - Offset curettes to facilitate access to the contralateral side of the disc space
  - Rasps, ring curettes, and reverse curettes to assist in endplate preparation
  - Osteotomes or box chisels to improve access to the interbody region when the disc space is narrowed posteriorly
  - Long straight and upbiting pituitary rongeurs for débridement of the interbody region

- After creation of the annular window, typically shavers or dilators of increasing size are serially introduced into the disc space and rotated (TECH FIG 3C,D).

- Lateral fluoroscopy can be helpful in determining the proper depth of penetration into the disc space. The anterior and anterolateral annulus should be palpated by the instrument and never violated, or catastrophic vascular injury could occur.

- Instruments used within the disc space are typically marked so that they are not overinserted to avoid potentially catastrophic violation of the anterior annulus. It is helpful to preoperatively estimate disc space length (posterior to anterior) on MRI or CT scan to have an idea of how far the instruments can be inserted.

- After dilation and shaving, a combination of curettes and rongeurs is used to perform a thorough discectomy and endplate preparation down to bleeding bone (TECH FIG 3E,F).

- Care should be taken not to violate the endplates in regions expected to load share with the interbody implant as this can make implant placement difficult and lead to settling of the structural graft.

- Several TLIF techniques do call for perforation of the endplates to expose cancellous bleeding bone in
TECHNIQUES

non-load-sharing interbody regions, using osteotomes for the anterior portion of the disc space or curettes and awls for other areas.

Because of the concave nature of the endplates, it is sometimes necessary to use osteotomes or box chisels to remove a rim of bone from the posterior aspect of the vertebral bodies to improve access to the disc space and allow for placement of a properly sized graft (TECH FIG 3G). The surgeon should remember that aggressive removal of the posterior lip may lead to a greater risk of implant backout with root compression.

On completion of the discectomy and endplate preparation, exposed bony endplates should be visible on the cephalad and caudal vertebral bodies.

To minimize the risk of neurologic injury and postoperative dysesthetic pain, several recommendations should be followed during the disc space preparation and graft insertion:

- Retraction on the neurologic elements should be minimized, and it should be released intermittently throughout the procedure.
- The thecal sac should never be retracted across the midline of the spinal canal.
- Particularly in revision cases, the neurologic elements should be carefully mobilized off the floor of the canal and disc space before retraction.
- Implants should be selected that can be inserted without excessive neural retraction.
- This can be an issue with use of threaded cylindrical cages because the height and width of the device must be equal; consequently, a cage of the appropriate height might be too wide to be safely inserted.
Graft Placement

- A variety of interbody grafting techniques have been described for use in the TLIF procedure:
  - Placement of two vertical fibular allografts or vertical titanium mesh cages posteriorly in the disc space with cancellous graft packed anteriorly (TECH FIG 4A)
  - Use of an oblique threaded cylindrical cage or machined cortical allograft bone dowel (TECH FIG 4B)
  - Use of an obliquely placed rectangular PEEK cage or bullet-shaped cortical allograft
  - Placement of a curved titanium cage, PEEK cage, or machined cortical allograft anteriorly and as centrally as possible within the disc space, with cancellous graft placed behind the device (TECH FIG 4C)

- While it has been shown that anterior cage placement is biomechanically superior to posterior cage placement, studies comparing the clinical efficacy of these various techniques do not exist.

- When choosing an interbody graft and grafting technique, surgeons should consider several factors:
  - Ability to insert the device without requiring excessive neurologic retraction
  - Volume of cancellous graft that can be packed within and around the cage or allograft
  - The effect of the graft’s position and shape on the ability to restore lordosis with later compression of the posterior instrumentation

- The remainder of this section will describe the technique in which a single curved titanium or PEEK cage or allograft is placed anteriorly and centrally within the disc space.

- After endplate preparation, graft trials should be used to determine the proper size for the interbody spacer (TECH FIG 4D). Fluoroscopic imaging should be used to confirm proper sizing of the trial.

- The anterior and lateral aspects of the disc space should then be tightly packed with morselized graft material.

  - Several options are available for use as morselized graft material, including autogenous iliac crest bone graft, local bone graft from the removed facet and lamina, allograft corticocancellous bone, allograft demineralized bone matrix, ceramic bone graft extenders, and bone-inducing substances such as bone morphogenetic protein.

  - The choice of graft should depend on surgeon experience, host factors that may affect fusion, patient preference, cost, and availability.

  - Graft impactors should be used to maximize the amount of bone that can be placed into the interbody space. For the technique using a central and anteriorly placed cage, the anterior 25% of the disc space should be filled initially with tightly packed morselized graft material.

  - Before inserting the actual cage or graft, the trial should be reinserted to confirm that the morselized graft has not blocked the pathway for insertion of the structural graft.

  - The implant should then be inserted into the interbody space and placed anteriorly and as centrally as possible.

    - Implant position should be confirmed with AP and lateral fluoroscopy during insertion.

    - Straight and offset impactors can be used to facilitate proper cage positioning.

    - Additional morselized graft material should then be packed into the posterior aspect of the disc space behind the implant (TECH FIG 4E,F).

**TECH FIG 4** • A–C. Several of the TLIF options available for graft type and position. A. Vertical cages or grafts placed posteriorly within the disc space with cancellous graft packed anteriorly. B. A single oblique threaded cage or graft. C. An anteriorly and centrally placed cage with cancellous graft placed posteriorly. D. Trial insertion to ensure that the appropriately sized device will fit and that cancellous graft packed into the disc space has not obstructed the pathway. E. Structural graft in place anteriorly with cancellous graft packed in the remaining portion of the disc space. F. Postoperative sagittally reconstructed CT scan demonstrating bone graft anteriorly, posteriorly, and within a titanium TLIF cage. (D–F, Courtesy of Synthes Spine.)
Compression and Posterolateral Grafting

- With the implant in place, distraction is released from the spinous processes or pedicle screws. Compression is then applied to the pedicle screw construct and the locking nuts are finally tightened.
- Compression both loads the anterior implant and restores lordosis to the spine.
- The contralateral spinous processes, lamina, facet joint, and transverse processes should then be decorticated (ideally the transverse processes were decorticated at the time of screw insertion).
- Morselized graft can then be placed into the contralateral interlaminar, facet, and intertransverse regions (TECH FIG 5).

- The interspinous ligament, if preserved, will serve to prevent graft migration into the exposed portion of the spinal canal and foramen.
- Some surgeons may also wish to place graft on the ipsilateral side in the intertransverse region, but care must be taken to avoid allowing graft to enter the spinal canal or compress the exiting nerve root.
- Final AP and lateral fluoroscopic images should be obtained.

Closure

- Before closure, final hemostasis should be obtained and the neurologic elements inspected to ensure that no graft material has fallen into the spinal canal.
- A Valsalva maneuver can also be performed to confirm the integrity of the dural sac.
- A standard layered closure over a drain is then carried out.

POSTERIOR LUMBAR INTERBODY FUSION

- Most of the technique for PLIF is similar to that described above for TLIF, except that a bilateral and more medial approach to the interbody space is used.
- This section describes the PLIF procedure by highlighting the differences between the TLIF and PLIF techniques.

- As noted in the exposure section, two PLIF exposure options are available (TECH FIG 6):
  - Extensive resection including wide laminectomy with bilateral complete facetectomies
  - Limited resection using bilateral laminotomies and medial facetectomies
The decision to use the wide laminectomy with total facetectomies is affected by several considerations:
- It provides maximal exposure and minimizes the amount of neural retraction necessary to place the interbody grafts or implants. This is essentially a bilateral TLIF.
- It should be strongly considered when fusing levels with a smaller interpedicular distance, such as in patients of short stature and in the upper lumbar spine.
- It results in iatrogenic instability and therefore must be supplemented with pedicle screw instrumentation. Even with pedicle screws, a bilateral PLIF represents a more unstable situation. In patients with poor bone quality, the pedicle screws can loosen and lead to instability of the construct, with possible cage migration.
- It eliminates the ability to fuse the facet joints posteriorly and reduces the host bone contact area available for the posterolateral fusion.
- Limited resection using bilateral laminotomies and medial facetectomies:
  - Preserves the segment’s biomechanical stability by preserving the spinous processes, the interspinous ligaments, and most importantly the lateral half of the facet joints and associated pars interarticularis
  - Must be employed for cases in which posterior instrumentation is not being used
  - May be difficult in patients with a tall disc space as there may not be enough room for passage of the larger interbody graft required without more extensive resection of the facets
  - Should only be attempted by surgeons very familiar with the PLIF procedure as additional neural retraction is necessary, with a consequent higher risk of neurologic injury
- After the exposure, pedicle screws are inserted and disc space distraction is applied as described for the TLIF procedure.

The PLIF procedure can be performed without pedicle screws if one uses the limited resection technique during exposure and care is taken not to destabilize the segment.

**Laminotomy and Partial Facetectomy**
- If the partial resection technique is being used, a laminotomy is performed by using curettes to detach the ligamentum flavum from each of the adjacent lamina as well as the superior articular process of the caudal vertebra.
- Kerrison rongeurs are then used to remove lateral portions of the adjacent lamina and the medial half of the superior and inferior articular processes.
- This process should be repeated bilaterally and should result in working windows for approaching the disc space on each side of spinal canal.
- When using the limited resection technique, care should be taken to preserve the spinous process, interspinous ligaments, lateral pars, and lateral half of the facet joints.
- As in the TLIF procedure, the exiting and traversing nerve roots need to be identified and appropriate caution used to avoid traumatizing these sensitive neurologic structures during the procedure. To minimize root injury, one should remove enough lateral bone to be able to access the disc space without major retraction of the traversing root.
- The wide laminectomy and bilateral facetectomy technique simply involves enlarging the above approach.
- Resection of the spinous process and interspinous ligaments medially will improve the ability to retract the thecal sac toward the midline.
- For a maximally sized working window, total facetectomies can be performed to allow for more lateral access to the disc space (see Fig 1A).
- After exposure, the posterolateral annulus can be accessed through the previously described triangular zone cephalad to the pedicle of the inferior vertebra, medial to the exiting nerve root, and lateral to the traversing nerve root and thecal sac (see Tech Fig 2C).
- Epidural veins are carefully coagulated and divided in the same way as described for the TLIF procedure.

**Disc Space Preparation**
- Disc space preparation is performed in an identical fashion as described above for the TLIF procedure except that bilateral annular windows are created somewhat more medially than for a TLIF.
- The thecal sac and traversing nerve root are mobilized medially, and a combination of shavers, curettes, and rongeurs is used to perform a thorough discectomy down to exposed endplate.
- In noninstrumented PLIF procedures, achieving adequate interbody graft contact area is critical to reduce the risk of graft subsidence.
- Closky et al demonstrated that in patients of average bone density and size, interbody graft contact area should exceed 6.2 cm² or an area roughly 2.5 × 2.5 cm.
### PEARLS AND PITFALLS

#### Indications
- As in all lumbar fusion surgeries, clinical success will depend largely on proper patient selection.
- Fusions performed primarily for discogenic back pain have a limited success rate, and realistic expectations will enhance patient satisfaction with the procedure.
- Revision procedures with extensive epidural scarring are technically challenging and benefit from a more lateral approach to the disc space to minimize retraction of neurologic elements typically surrounded by fibrous tissue.

#### Interbody access and preparation
- Distraction techniques are used to neutralize the alignment of the adjacent endplates as much as technically feasible.
- Concave endplates may require use of an osteotome or box chisel to facilitate access to the disc space and allow for placement of a properly sized graft.
- An array of interbody preparation instruments, including offset curettes, must be available to facilitate comprehensive removal of endplate cartilage and disc material.
- Since achieving an interbody fusion is critical to the success of the procedure, adequate time and effort must be spent in disc space preparation. The surgeon must not rush interbody preparation.
- To avoid serious endplate violation, care must be taken to maintain a parallel trajectory to the disc space when working with instruments in the interbody region.

#### Neurologic injury
- Identifying the location of the exiting nerve root is a vital step in the procedure and should occur before incising the annulus.
- Insufficient laminectomy can result in poor visualization and excessive neural retraction with inadvertent neurologic injury.
- Exiting nerve roots with a more acute angle of takeoff from the thecal sac can result in a smaller triangular working zone and should be gently retracted laterally.
- Medial retraction of the thecal sac and traversing nerve root should be minimized and must never cross the midline.
- Neurologic retraction should be released frequently to allow for reperfusion of these sensitive structures.
- Free run electromyographic monitoring can provide live feedback and help reduce the risk of neurologic injury from overzealous neurologic retraction.
- Great care must be taken to account for the dura and neurologic elements every time that an instrument or graft is inserted into the disc space.
- Should significant difficulties arise such as obstructing anomalous neural anatomy, major epidural bleeding, or a complex dural tear, one must be willing to abandon the interbody portion of the fusion rather than risk causing a catastrophic injury.
Epidural bleeding

- Epidural bleeding can be troublesome in the posterior annular region, and use of hemostatic agents such as Gelfoam, Floseal, or Surgiflo should be strongly considered.
- Great care must be taken to identify the neurologic structures when using bipolar cautery.
- Should a dural tear occur, it should be repaired as soon as technically possible, as reduced intrathecal pressure will produce engorgement of the epidural veins with significantly more bleeding.

Graft placement

- Bony resection must allow sufficient access to the interbody region to allow placement of an adequately sized graft.
- Graft type should be chosen carefully in situations where access to the disc is limited or a tall disc space exists.
- Due to their narrower widths, rectangular grafts or cages can be inserted more easily into a tall disc space than cylindrical grafts, which require a larger transverse exposure.
- Fluoroscopy and offset impactors should be used during graft insertion to facilitate optimal final implant position.

POSTOPERATIVE CARE

- The patient is typically mobilized out of bed the day after surgery.
- Postoperative bracing is typically not required for the TLIF or instrumented PLIF procedures but can be used according to surgeon preference.
- Most physicians prefer to use a thoracolumbosacral orthosis during the postoperative period for noninstrumented PLIF procedures.
- Serial radiographs are used to assess for fusion.

OUTCOMES

- Fusion rates for the PLIF and TLIF procedures are similar, with studies finding rates of obtaining a solid arthrodesis varying between 89% and 100%. Several recent larger studies have reported fusion rates above 95%. 7,10,11
- While clinical success rates vary between studies, most series report similar outcomes with PLIF and TLIF as for anterior interbody and combined anterior and posterior fusion procedures.
- Most of the studies on PLIF and TLIF using visual analog scale (VAS) and Oswestry Disability Index (ODI) scores as outcome measures demonstrate an overall patient satisfaction rate of about 80% with the procedure. 4,17,8,14
- Longer-term studies indicate that the results of PLIF and TLIF procedures tend to be durable once a solid arthrodesis has been achieved.

COMPLICATIONS

- Neurologic injury is an uncommon complication of PLIF and TLIF and has been reported to occur in between 0% and 4% of patients. Many of these injuries represent a neuropraxia due to excessive nerve root retraction and resolve spontaneously.13,15
- Dural tears are a more common complication and have historically been reported to occur in 0.5% to 18% of PLIF and TLIF procedures.
- The dural tear rate appears to be significantly lower with the TLIF procedure compared to the PLIF, likely related to the fact that less neural retraction is necessary when using the TLIF’s more lateral approach to the disc space. 3
- More recent studies demonstrate a trend toward much lower rates of dural tears in both PLIF and TLIF procedures, with a reported incidence in the range of 1% to 5%.
- Implant migration or failure is a rare complication in the TLIF procedure but has been reported to occur in up to 2.4% of cases in which a noninstrumented PLIF is performed. Properly sizing the interbody implants and fully packing the disc space with graft material can help reduce the risk of this complication.
- Other complications of posterior lumbar fusions that are not specific to the PLIF and TLIF procedure include wound infection, excessive bleeding, pedicle screw malposition, and epidural hematoma.

REFERENCES

DEFINITION

- Anterior thoracic approaches provide a means of decompression, stabilization, and fusion for a variety of spinal pathologies, such as deformity, trauma, infection, tumors, and disc herniations.

ANATOMY

- The thoracic vertebral bodies are heart-shaped in the anteroposterior plane.
  - The thoracic pedicles are oval and are larger superoinferiorly than mediolaterally.
  - The average height is 8 to 15 mm and the average width is 3 to 10 mm.
  - The medial cortex is the thickest; however, there is no epidural space between the medial cortical edge and the dura.16
  - The facet joints are situated more anteriorly and articulate superiorly and inferiorly with a rib. As the transition from the thoracic to lumbar spine occurs, the thoracic vertebrae begin to resemble the lumbar vertebrae and the facets change from a frontal orientation to one that is more lateral.

PATHOGENESIS

Intervertebral Disc Herniation

- Seventy-five percent of thoracic disc herniations occur between T8 and L1. They are classified as central, centrolateral, lateral, or paramedian.
  - Most herniations occur central or centrolateral and are often calcified.
- The spinal canal in the thoracic spine is relatively small.
  - Neurologic consequences occur from direct anterior compression of the spinal cord from a herniated disc. There can be posterior displacement of the cord and local vascular insufficiency.

Infection

- The mechanism of spinal infections is controversial. Proposed routes of infection include hematogenous spread from other infected foci, local extension from nearby infections, and direct inoculation.
  - The two proposed routes of hematogenous spread are venous and arterial.
  - Advocates of venous hematogenous spread argue that organisms are carried to the spine via the plexus of Batson, similar to the mechanism of tumor metastasis.5
  - Proponents of arterial hematogenous spread note that the metaphyseal bone near the anterior longitudinal ligament is an area where infections typically begin. This region has an end-arteriole network that is susceptible to bacterial seeding.19

Tumor

- Most spine tumors are of metastatic origin. The spinal column is the most frequent site of skeletal metastasis.18
- Malignant cells are carried to the spine through the valveless extradural venous plexus of Batson.2,8 A recent anatomic model suggests that malignant cells can also metastasize through the segmental arteries.20

Trauma

- The articulation of the vertebral column, ribs, and sternum makes the thoracic spine relatively stable.1
- High-energy injuries are frequently required to produce injury to the thoracic spine.
- Forces associated with injury are axial compression, flexion, lateral compression, flexion–rotation, shear, flexion–distraction, and extension.

NATURAL HISTORY

Intervertebral Disc Herniation

- Wood et al described 20 patients with asymptomatic thoracic disc protrusions followed by magnetic resonance imaging (MRI).21 All patients remained asymptomatic at an average of 26 months, and most disc herniations were smaller or unchanged on repeat MRI.
  - It is unknown how often asymptomatic thoracic herniations become symptomatic.
- Brown et al reported on 55 patients with 72 thoracic disc herniations.3 Fifty-four were treated initially with conservative therapy and 15 eventually required surgery. Nine of 11 patients with lower extremity complaints went on to have surgery. Two patients had myelopathy and were treated surgically. All 55 patients ultimately returned to their previous level of activity.
  - Patients with lower extremity symptoms and myelopathy are likely to require surgical intervention.

Infection

- Vertebral osteomyelitis is rare and accounts for 2% to 4% of all cases of osteomyelitis.
  - Staphylococcus aureus is the most common organism, accounting for almost 50% of pyogenic infections.5
  - The incidence is rising as a result of a growing immunocompromised and elderly patient population, increased intravenous drug abuse, and an increase in invasive diagnostic and therapeutic procedures.
  - Before medical and surgical treatment, spinal osteomyelitis carried a mortality rate of greater than 70%.10 The advent of antibiotics and anterior spinal débridement techniques has reduced mortality to less than 15%.6,13
- Carragee reported on 72 patients were treated nonoperatively with antibiotics.6 Over 33% of them required surgical débridement. Results related to patient age and immune status.
Tumor
- Over 90% of spinal tumors are metastatic lesions with a distant primary source.
- Primary tumors from the breast, prostate, lung, kidney, and thyroid are most likely to metastasize to the vertebral column.18
- Tumors that affect the anterior elements of the spine can be benign or malignant.
- Benign primary tumors that have a predilection for the anterior elements include giant cell tumors and hemangiomas. Malignant tumors that commonly affect the anterior elements include osteosarcomas, chondrosarcomas, myelomas, and lymphomas.15
- Improved diagnostics have allowed for more accurate diagnosis and improved staging.9
- Chemotherapy and radiotherapy have improved survival and local control.14
- Treatment goals include preservation of neural function, spinal stability, margin-free tumor resection, and correction of deformity.

Trauma
- Fractures of the thoracolumbar spine are the most common spinal injuries.
- The thoracic spine configuration of vertebrae, sternum, and ribcage confers an inherent stability.1
- Injuries to this region require significant force, and unstable injuries are usually a result of high-energy injuries such as motor vehicle accidents, falls from heights, and crush injuries.
- Patients can have associated injuries such as pneumothoraces, pulmonary contusions, and vascular injuries.
- Although most thoracic injuries do not involve neurologic deficit, complete neurologic deficits are more common with thoracic spine injuries due to the small neural canal, the tenuous blood supply, and the high energy needed to cause injury.4

PATIENT HISTORY AND PHYSICAL FINDINGS
- Neurologic status is examined.
  - Manual motor testing
  - Pin-prick and light touch sensory examination may help to localize the cord level of injury based on dermatome.
  - Babinski reflex and clonus are upper motor neuron signs.
  - Reflex examination of the patellar and Achilles tendons: hyperactivity is an upper motor neuron sign.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- It is often useful to obtain an MRI and a CT-myelogram preoperatively. MRI is the key radiologic study to confirm the diagnosis and localize pathology. Plain CT scans are helpful in delineating bony anatomy.
- A plain CT scan should be obtained in concert with MRI on every patient with a destructive bony process, such as tumor or infection, to preoperatively assess the degree of bony loss and determine the optimal strategy for reconstruction.
- CT-myelography may be needed if MRI scans cannot be obtained or if quality of the MRI is suboptimal due to patient movement, metal artifact from prior implants, or other factors.
- CT can detail ossification of the posterior longitudinal ligament or ligamentum flavum.
- CT-myelography can also clarify whether cord compression is primarily anterior secondary to a disc fragment, or circumferential due to stenosis.

DIFFERENTIAL DIAGNOSIS
- Spinal tumors
- Infections
  - Transverse myelitis
  - Ankylosing spondylitis
  - Fractures
  - Intercostal neuralgia
  - Herpes zoster
  - Cervical and lumbar herniated discs
  - Disorders of thoracic and abdominal viscera
  - Amyotrophic lateral sclerosis
  - Multiple sclerosis
  - Arteriovenous malformations

NONOPERATIVE MANAGEMENT
Intervertebral Disc Herniation
- In the absence of myelopathy, most patients can be treated conservatively.
- A conservative treatment plan should include nonsteroidal anti-inflammatories, rest, activity modification, and physical therapy focusing on trunk stabilization.3
- Other options include intercostal nerve blocks and pharmacotherapy such as narcotics, tricyclic antidepressants, serotonin-reuptake inhibitors, and certain antiepileptics.

Infection
- Vertebral infections should be treated nonoperatively with culture-specific antibiotics and spinal immobilization.
- Open or CT-guided biopsy can aid in targeting appropriate antibiotic treatment.
- Treatment frequently involves 6 weeks of parenteral antibiotics followed by a course of oral antibiotics.
- An infectious disease consultant can help guide the antibiotic regimen.
- External immobilization with an orthosis can help stabilize the spine, decrease pain, and prevent deformity.
- Bracing is particularly important in patients with greater than 50% destruction of the vertebral body since they are at greater risk for deformity.7
- Response to treatment can be followed clinically with erythrocyte sedimentation rate, C-reactive protein, and a complete blood count.

Tumor
- A multidisciplinary approach including a neuroradiologist, pathologist, oncologist, and spine surgeon is used to treat spinal tumors.
- A CT-guided biopsy can help establish a diagnosis in 76% to 93% of lesions.7,18
- Metastatic lesions that do not compromise spinal stability and without rapid neurologic progression can be managed nonoperatively.18
- Nonoperative treatment can include radiation, chemotherapy, embolization, and bracing.
Most primary spinal tumors cannot be treated nonoperatively.

Trauma
- Most thoracic and thoracolumbar spine injuries can be effectively treated nonoperatively.
- Conservative treatment can include recumbency, bracing, and pain management for patients without neurologic deterioration and with a structurally stable injury.11,17
- Decubitus ulcers, thromboembolism, urinary tract infections, and late pain are complications reported with nonoperative treatment.12

SURGICAL MANAGEMENT
- Indications for discectomy
  - Progressive myelopathy due to anterior compressive lesions
  - Lower extremity weakness or paralysis
  - Radicular pain refractory to conservative therapy
  - Deformity correction
- Indications for corpectomy
  - Fractures with anterior spinal cord compression
  - Metastatic or primary thoracic tumors
  - Osteomyelitis
  - Sequestered disc herniations that have migrated behind the vertebral body
  - Ossification of the posterior longitudinal ligament
- Indications for bone grafting and cage or allograft placement
  - Although somewhat counterintuitive, anterior spinal infections can be successfully managed with allograft, cage, or instrumentation reconstruction if a thorough debridement of infected tissues is performed and postoperative antibiotics are administered
  - Tumor
  - Trauma
  - Degenerative disease
  - Deformity correction (scoliosis, kyphosis)
- Indications for polymethylmethacrylate (PMMA) use
  - Anterior column reconstruction of tumors in patients with a life expectancy of less than 1 year
  - Patients in whom the use of radiation or chemotherapy is anticipated
- Indications for use of solid rod instrumentation
  - Patient under 30 years of age
  - Thoracic and thoracolumbar curves of less than 65 degrees (Cobb angle)
  - Thoracic or lumbar compensatory curves that correct to less than 20 degrees with side bending
  - Hypokyphosis (less than 20 degrees from T5 to T12)
  - Refer to Chapter SP-3 for preoperative planning, patient positioning, and approach discussions.

THORACIC DISCECTOMY
- After elevating the articular ligaments of the costotransverse and costovertebral articulations, the remaining rib head is excised (TECH FIG 1).
- The superior edge of the pedicle of the caudal vertebra is resected with a rongeur to expose the dural tube.
- To find the disc herniation, the surgeon follows the superior edge of the pedicle to the vertebral body and disc space.
- The disc herniation is removed using small angled curettes and pituitary rongeurs.
- Discectomy can be facilitated by removing a small portion (1 to 2 cm) of the adjacent vertebral bodies. If the disc is extremely calcified or has migrated behind the vertebral body, it is helpful to perform hemicorpectomies of the adjacent vertebral bodies.
- The portion of the disc that lies away from the ventral aspect of the spinal cord should be removed first. Once a cavity is created by removing this initial disc and bone, the rest of the disc can be removed into this cavity, ensuring that all forceful maneuvers are directed anteriorly away from the thecal sac.
- We prefer to keep the posterior longitudinal ligament (PLL) intact whenever possible, as its removal often results in substantial epidural bleeding. We will pass an elevator or nerve hook through a rent in the PLL if one is present to ensure adequate decompression from pedicle to pedicle. If the PLL needs to be removed, we use bipolar cautery to cauterize the PLL and then carefully remove it with either a Kerrison or a combination of pituitary rongeur and curette.
**THORACIC OR THORACOLUMBAR CORPECTOMY**

- The posterior aspect of the vertebral body is identified.
- Discectomy is performed above and below the level of the corpectomy.
- The lateral annulus is incised using a no. 10 blade to the anterior midline.
- An elevator is then used to separate the disc from the endplates.
- Discectomy is completed using curettes and rongeurs.
- Attention is turned to the vertebrectomy. Using a 4-mm burr, the surgeon removes most of the bone from the vertebral body.
- Corpectomy is completed by removing the remaining bone with a rongeur (TECH FIG 2).
- Depending on the nature of the pathology, the PLL may need to be removed for the purposes of decompression.
- For retropulsed fracture fragments, the fragments are first thinned using a high-speed 4-mm ball-tipped burr.

Then a thin, sharp curette is used to peel the fragments away from the dura and into the created trough.

- It is important to work quickly but carefully at this point as there can be a significant amount of epidural bleeding.
- The posterior cortical fragments are removed from the contralateral (deep) side of the canal first so that the bulging dura will not obscure the rest of the fragments.
- Decompression is adequate when the dura can be seen bulging into the corpectomy trough and the spinal canal has been decompressed throughout its complete width.

**Plating**

- A flat surface is prepared for the plate by removing lateral endplate prominences and rib heads with a high-speed burr.
- Using an awl insertion guide, a posterior bicortical thoracic bolt is placed at the cephalad and caudal fixation levels.
- The trajectory should be parallel to the endplate and angled slightly anteriorly to avoid penetrating the canal (TECH FIG 3A).
- If sagittal correction or interbody graft placement is needed, distraction is performed on the endplates using a lamina spreader.
- A correct-length plate is applied over the bolts without extending into the adjacent disc spaces (TECH FIG 3B,C). Nuts are applied loosely to secure the plate to the posterior bolts.
- Using a drill or awl, correct-length anterior screws are placed angling slightly posteriorly.
- In general, bicortical screws are preferred because the cancellous bone of the vertebral body provides relatively weak purchase, especially in patients with tumors or infections.

**TECH FIG 2** • Corpectomy site.

**TECH FIG 3** • Application of plate and screws. **A.** Osteophytes are removed, and a trajectory is planned parallel to the endplate and angled slightly anteriorly to avoid penetration of the canal. **B.** Nuts secure the posterior bolts, and screws are applied anteriorly. **C.** It is important for the screws to be a safe distance from the dural covering of the spinal cord.
SCREW–ROD INSTRUMENTATION

- Use of an anterior screw–rod construct allows for correction of coronal plane deformity through fusion of fewer spinal motion segments compared with posterior instrumentation.
- The entry position for the anterior vertebral screws is determined based on the location of the vertebral foramen, as this identifies posterior body cortex.
- The surgeon inserts the most cephalad and caudad screws first in the midlateral vertebral body at the same distance from the posterior cortex (TECH FIG 4).
- The screw tips should engage the far cortex of each vertebra and should be directed toward the posterolateral corner of the vertebra.
- The rest of the screws are placed in similar fashion.
- The rods are inserted as directed by the particular system, and alignment is corrected before tightening.

BONE GRAFTING AND CAGES

- It is of utmost importance to prepare an adequate fusion bed.
- A thorough decortication is performed.
- Although placement of the graft on preserved bleeding subchondral endplates is preserved, creating a slot or peg hole in the adjacent vertebral bodies can help to prevent graft extrusion.
- Before graft placement, kyphotic deformity can be corrected by distracting adjacent vertebrae.
  - Extreme care must be taken to avoid injury to the adjacent endplates during distraction, especially in patients with osteoporosis or other states with compromised bone quality (tumors, infections).
- After the graft has been anchored, compression locks the graft in position.
- If tricortical iliac crest bone is used, we prefer to have the cortical smooth surface face the spinal canal.
- Single-level corpectomy defects can be supported with tricortical iliac crest grafts, whereas larger defects are better stabilized with autogenous fibular strut grafts or shaft allografts.
- Depending on the size of the patient, humeral shafts often provide the best fit in the thoracic spine.
- For cage placement, the ends of the cage can be trimmed to create the necessary cage configuration (TECH FIG 5A).
  - Alternatively, stackable cages (eg, those made of PEEK) can be measured to fit the space.
- The packed cage is implanted between the distracted adjacent endplates (TECH FIG 5B).
- The cage is stabilized when the distraction is released.
- Bone graft should be packed in and around the cage.

Polymethylmethacrylate

- PMMA may be used in patients with spinal tumors who have poor life expectancy, or who are unlikely to heal anterior bone grafts due to poor bone quality or healing potential.
POSTOPERATIVE CARE

- Chest tubes remain until output is less than 150 mL over 24 hours.

COMPLICATIONS

- The exiting nerve root can be injured while removing the pedicle.
- Vascular injury
- Intercostal neuralgia
- Atelectasis
- Neurologic injury
- Wrong-level surgery
- Significant bleeding can be encountered when entering the epidural space.

REFERENCES

DEFINITION
- Lumbar disc degeneration is an age-related process heralded by a loss of disc height and gradual changes to the biochemical structure and biomechanical behavior of the intervertebral disc.
- Disc degeneration is not painful in most individuals, but in some patients, the degenerative changes do become painful and lead to the clinical entity known as degenerative disc disease (DDD). It is unclear why disc degeneration is painful in some but not in most.
- The etiology of DDD is multifactorial, including genetic and environmental determinants.
- “Discogenic pain” is the term used to describe pain due to a degenerative disc.

ANATOMY
- The intervertebral disc is composed of the outer annulus fibrosus and the inner nucleus pulposus (FIG 1A).
- The vertebral endplate is composed of cancellous bone in the center and strong, dense, cortical bone along the periphery.
- MRI provides information about the extent of hydration within the disc nucleus. The degenerated disc nucleus will have low signal characteristics (appear dark) on T2-weighted MRI images (FIG 1B).
- Dark discs on MRI do not necessarily correlate with symptomatic low back pain.

PATHOGENESIS
- Various mechanisms have been proposed to explain disc degeneration with age:
  - Reduced nutrition and waste transport
  - Decreased concentration of viable cells
  - Loss of matrix proteins, proteoglycans, and water
  - Degradative enzyme activity
  - Fatigue failure of the matrix
  - Herniated nucleus pulposus
- Alterations to the vertebral endplate microenvironment such as venous pooling and reduced oxygen tension are additional factors.
- Nicotine has known detrimental effects on the intervertebral disc, perhaps via these mechanisms.
- Several factors have been implicated in the generation of discogenic pain: altered disc structure and function, release of inflammatory cytokines, and nerve ingrowth into degenerated discs, which under normal conditions are only minimally innervated in the outermost portion of the annulus.

NATURAL HISTORY
- Radiographic findings of disc degeneration typically appear around age 30.
- Posttraumatic disc herniations, vertebral endplate injuries, and genetic factors may predispose patients to earlier presentation.
- As structural changes occur within the intervertebral disc, associated changes in the vertebral body endplate become apparent:
  - Anterior, lateral, or posterior osteophyte formation
  - Schmorl nodes, cystic cavities, along the endplate can be visualized
  - Endplate sclerosis
- The degenerative changes at the level of the disc, bony endplate, and ultimately the posterior facet-joint complex ultimately restrict motion at the affected level or levels. At this stage, patients will typically complain more of back stiffness and soreness rather than pain. Neurogenic claudication due to narrowing of the spinal canal and spinal stenosis typically becomes more limiting than complaints of back pain.
- The final stage in the natural history of disc degeneration is autofusion.
- Patients should be counseled that disc degeneration itself is an inevitable process of aging and that any back pain experienced could, but may not necessarily, be associated with the disc degeneration.
- The overwhelming majority of patients have only occasional episodes of low back pain. Long-term disability resulting from DDD is rare.

PATIENT HISTORY AND PHYSICAL FINDINGS
- No pathognomonic history or physical examination findings exist for the diagnosis of lumbar DDD.
- Discogenic back pain is typically worst in situations in which an axial load is applied to the lumbar spine, as in prolonged sitting or standing with a forward-bent posture (ie, washing dishes, vacuuming, shaving, or brushing teeth).
- Conversely, positions such as side-lying (ie, the fetal position) or floating erect in water place the least amount of strain across the intervertebral disc and should therefore provide some pain relief.
- Leg pain (in the absence of neural compression), if present, is nonradicular and “referred” in that it does not follow lumbar dermatomes into the lower leg and is not typically associated with loss of motor power, reflex changes, numbness, or tingling.
- Patients will occasionally describe a discrete traumatic disc injury in which they first experienced back pain. Imaging studies that depict an old endplate fracture above or below a degenerative disc help corroborate this history.
- Loss of truncal musculature fitness from abdominal wall hernias, obesity, and prior abdominal wall surgery (ie, rectus
muscle transfer procedures) may worsen discogenic back pain.

- Other causes of back pain should be sought in the history, physical examination, and imaging studies, including muscular strain, spondylolysis or spondylolisthesis, herniated nucleus pulposus, compression fracture, pseudarthrosis, tumor, and discitis.
- Patients with isolated DDD by definition should have a normal neurologic examination.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standing plain radiographs
  - Lateral radiographs allow for measurement of the intervertebral disc height and allow comparison to other lumbar intervertebral discs (FIG 2A).
  - Anteroposterior (AP) radiographs allow for determination of asymmetric, coronal plain disc degeneration, which may be a precursor to lumbar degenerative scoliosis.
  - Flexion-extension radiographs may be helpful in diagnosing an occult spondylolisthesis or spondylolysis.
  - MRI provides excellent visualization of the discs, the degree to which they have degenerated, and the relationship of the discs to the adjacent endplate and surrounding neurologic structures (FIG 2B).
  - Provocative discography attempts to reproduce the patient’s typical back pain by pressurizing the disc with normal saline. The patient needs to be awake to provide subjective feedback as to the quality and intensity of the pain. Architectural changes to the disc are inferred by contrast administered with the saline.
  - CT discography provides more detailed information about the disc morphology after contrast administration (FIG 2C).

- Normal laboratory tests, including complete blood count, erythrocyte sedimentation rate, and C-reactive protein, can help rule out a disc space infection; severe disc degeneration can sometimes mimic infection radiologically.

DIFFERENTIAL DIAGNOSIS

- DDD
- Discitis
- Pyogenic vertebral osteomyelitis

NONOPERATIVE MANAGEMENT

- DDD is analogous to hip and knee osteoarthritis in that the intervening cartilage (in the case of the disc: collagen, water, and proteoglycans) fails under compressive loads.
- Weight reduction and activity modification (avoidance of exacerbating activities) may be effective first-line treatments.
- Nonsteroidal anti-inflammatory medications
- Acupuncture or massage therapy
- Physical therapy with aquatic or dry land exercises
- Gentle pelvic traction
- Methylprednisolone (Solu-Medrol) taper
- Epidural injections
- Narcotic medications for severe episodes of pain

SURGICAL MANAGEMENT

- Indications
  - Discogenic back pain refractory to nonoperative management
  - Discitis with pyogenic vertebral osteomyelitis refractory to nonoperative management
  - Spinal deformity requiring radical discectomy
  - A thorough and complete discectomy improves the effectiveness of anterior interbody fusion by creating a wide surface area of exposed bone.
Interbody reconstruction and fusion can be accomplished by a variety of methods, including structural autogenous bone graft (iliac crest or fibula), structural allograft (ie, femoral or humeral ring, femoral head, machined bone dowel), or synthetic device (titanium, PEEK, carbon-fiber, composite) packed with cancellous bone or collagen sponges impregnated with bone morphogenic protein 2 (BMP-2).

Regardless of the method used, prerequisites are that the interbody spacer be strong enough to resist intervertebral compressive loads and provide an appropriate biologic environment for healing.

The particular interbody fusion device of choice (eg, Bagby-Kuslich [BAK; Zimmer Spine, Warsaw, IN], lumbar-tapered [LT] cage [Medtronic Sofomor Danek, Memphis, TN], Bengal carbon fiber cages [DePuy Spine, Raynham, MA]) is inserted with instruments designed for proper implantation.

BMP-2 has been approved by the U.S. Food and Drug Administration for anterior interbody application and has been shown to increase the fusion rate when compared to iliac crest bone graft.5

Preoperative Planning

Plain radiographs, MRI, or CT scans should be carefully evaluated for undiagnosed spondylolysis or spondylolisthesis, which may alter the surgical plan.

Templates can be used with plain radiographs or MRI scans to gauge the size of the final implant to be used.

Oversized implants can lead to undesired stretch on neurologic structures and reduced motion of lumbar disc replacements.

The level of the confluence of the common iliac veins into the inferior vena cava and the bifurcation of the aorta can be located on the axial MRI scans.

At L5-S1 the pubic symphysis occasionally precludes appropriate visualization and instrumentation of the disc space in patients with a deep-seated L5-S1 relative to the pelvis. Evaluation of the lateral radiograph with the pubis on the film is critical to visualize the trajectory into the disc space and avoid this miscalculation.

Positioning

See Chapter SP-4.

The patient is placed over an inflatable pillow over a 1-inch-thick foam pad, which is placed on the mattress of the operating table. The pillow allows for modulation of lordosis throughout the procedure and the foam pad props the patient up, allowing the arms to be tucked posteriorly, out of the plane of the spine during imaging.

Positioning over the break in the table allows for increased lordosis if needed.

The use of fluoroscopic C-arm imaging is crucial for appropriate patient and implant positioning. It is helpful to verify that adequate fluoroscopic imaging of operative landmarks can be achieved after the patient is positioned but before the incision is made.

Approach

See Chapter SP-4 on anterior lumbar approach.

Anterior retroperitoneal approaches will typically allow access to the lumbar discs from L2-3 to the sacrum.

The renal vessels limit more proximal extension of the exposure.

Lateral exposures to the lumbar spine are required for access to the L2 vertebra and above.
Chapter 17  ANTERIOR LUMBAR INTERBODY FUSION, DISC REPLACEMENT, AND CORPECTOMY 4637

ANTEOR LUMBAR RADICAL DISCECTOMY

Exposure

- Identify the intervertebral disc and mark the midline with a spinal needle or screw placed into the vertebral body (we prefer not to place a needle into the disc space because this may create unwanted disc injury) (TECH FIG 1A).
- Use AP and lateral fluoroscopic imaging to check the midline. The midline marker also serves to verify the spinal level.
- At L5-S1, retract the left common iliac artery and vein to the patient’s left and the right common iliac artery and vein to the right. At levels above L5-S1, the aorta and inferior vena cava must be mobilized to the patient’s right.
- The great vessels can be held in their retracted position using handheld Hohmann retractors, custom-designed pins, or K-wires, all of which can be advanced directly into the vertebral bodies (virtually eliminating the risk of vessel migration into the field of interest) (TECH FIG 1B).
- Alternatively, stainless-steel vein retractors or radiolucent retractors can be fixed to the arms of an abdominal retractor system (Omnif) or floating, Endo-ring-type retractor system. These blade retractors have the disadvantage of allowing vessel migration into the field by sliding under the retractor blades as motion occurs during the procedure. The advantage of the radiolucent retractors is that better visualization of the operative field is possible with fluoroscopy. In addition, blade-type retractors can be easily manipulated during the procedure without having to reinsert into the vertebral body.
- Attempt to retract the vessels as far lateral as you can to allow for the widest possible view of the intervertebral disc. Poor visualization at this stage will compromise the quality of the discectomy and any ensuing interbody device placement.

Removing the Disc

- Using a 10-blade on a long handle, incise the intervertebral disc starting laterally along the superior endplate and move toward midline. Always move away from the vessels to avoid an accidental lateral plunge into the great vessels. The blade should be inserted between the cartilage endplate and bone if possible, and we use both hands on the knife shank for optimal control and coordination (TECH FIG 2AB).
- A large, sharp Cobb elevator is then used to release as much of the cartilaginous endplate as possible from the superior and inferior endplates. By angling the Cobb blade toward the bone and pronating and supinating the hand, almost the entire disc (annulus and nucleus) can be removed, as if peeling an orange in one large piece (TECH FIG 2C).
- Long-handled no. 2 and no. 3 Cobb curettes are used to remove the remaining disc, taking the dissection all the way to the posterior longitudinal ligament (TECH FIG 2D). Systematic removal of endplate cartilage enhances thorough removal. Thus, start anteriorly on the superior endplate and move posteriorly. Then start anteriorly on the inferior endplate and move posteriorly.
- The curette will function much more effectively if it is used as a cutting instrument rather than a scraper. For this reason, we prefer that curettes be sharp, nonangled, and used with a pronating–supinating motion with the edge of the curette between the cartilage endplate and the endplate bone.
- The posterior longitudinal ligament is not routinely removed, but the posterolateral corners of the disc space must be thoroughly débrided of disc material for several reasons:
  - Periphery of the endplate is the strongest bone and therefore provides the most stable support of an interbody device.
  - Disc material that is left over can be pushed posteriorly into the epidural space, causing an iatrogenic disc herniation during implant insertion.
  - If anterior decompression of the neural foramen is one of the goals of surgery, visualization and removal of a herniated disc or disc–osteophyte complex will not be possible without proper visualization in this region.
The lateral extent of the discectomy is determined by the width of the device to be inserted, but care must be taken to maintain the width of the discectomy posteriorly as the natural tendency is to remove less disc laterally in the posterior portion of the disc space.

A lamina spreader can be gently distracted in the anterolateral interbody region to gain enhanced visibility of the posterior disc space (TECH FIG 2E).

Removal of a posterior or foraminal disc herniation can be accomplished by passing an angled Kerrison rongeur posteriorly and into the neuroforamen. Identification of the ventral aspect of the dura enhances the safety of this maneuver (TECH FIG 2F).

Epidural bleeding can be brisk during posterior disc removal, but thrombin-soaked Gelfoam gauze and removal of intervertebral distraction can be used to control it.

**TECH FIG 2 • A, B.** Direction of movement of the surgical blade. At L5-S1 the surgical field is within the bifurcation of the great vessels, so the surgical knife should always be directed toward the midline and inferiorly—away from vascular structures. At L4-5 and above, the vascular structures are retracted to the patient’s right, and therefore movements with the knife blade are directed to the patient’s left and inferiorly. C. A large Cobb is used between the disc cartilage and the vertebral body to remove as much as possible in one large piece. (continued)
Once the discectomy has been completed, disc space distractors are inserted to gauge the size of the final implant (TECH FIG 3A). Appropriate distractor size can be gauged by comparing the operative level with a normal disc above or below. In addition, the interface between the distractor and the bony endplate should be less than 1 mm. This ensures good interference fit of the final device.

For threaded devices such as the LT cage, a cannulated guide channel is inserted over the disc distractors. This working channel serves to prevent inadvertent migration of the great vessels into the disc space.

Endplate reamers are then inserted to appropriate depth as determined by lateral fluoroscopic imaging (TECH FIG 3B). Care should be taken to aim the reamer for the midportion of the disc space posteriorly on lateral fluoroscopy rather than through one endplate or the other.

Asymmetric reaming will result in excessive removal of one endplate compared to another and the final implant will be more likely to fail in subsidence. Because the reamer tends to follow the path of least resistance, an exceptionally sclerotic endplate will predispose one to asymmetric reaming by this mechanism.

Final threaded implants are then screwed into the appropriate depth and orientation (TECH FIG 3C,D). The first cage (in a dual-cage system) is inserted in the same trajectory as the reamers, and lateral fluoroscopic imaging during cage placement ensures that the cage is not placed too anteriorly or posteriorly. The cage should not
be inserted beyond the depth of the reamer or else the threads will strip and the cage will lose a large percentage of its fixation strength. 
- Saving the C-arm image of the final reamer depth allows the surgeon to reference this image when inserting the cage.
- The second cage is inserted using the first cage as a reference for trajectory and depth. Final images should be true AP and lateral projections showing the cage devices to be in good position. Overlapping pedicles on the lateral image will appear sharp, confirming true lateral positioning (TECH FIG 3E,F).

**LUMBAR TOTAL DISC REPLACEMENT**

**Determining Implant Size**
- Determine midline and the appropriate spinal level by inserting a bone screw, which will serve as a reference throughout the case. Obtaining true AP and lateral images is critical to ensure that the remainder of the instruments and devices can be referenced off these radiographic landmarks (TECH FIG 4A).
- Once the discectomy is completed, a sizing guide, or “lollipop,” is used to ascertain the size of the implant to be used (TECH FIG 4B). These guides vary in depth and width to conform to the size of the vertebral endplate.
- The endplate of S1 is often more shallow in the AP dimension than L5, and this may necessitate the use of a smaller implant at this level.
- The largest footprint that is still covered by the vertebra is chosen. This helps to ensure that the final device will be supported by the greatest percentage of peripheral cortical bone.
- The height and lordosis of the final implant are determined by trial wedges that fit into the interbody location (TECH FIG 4C–E). The vertebral endplates should be flush with the trials.
Implant Placement
- Grooves for a central keel or for fixation teeth are then cut. Make sure the central groove is in the midline and that the trajectory for the grooves is directly posterior and not angled (TECH FIG 5A,B).
- The final implant is then inserted (TECH FIG 5C,D). Double-check that the implant is the correct size and is inserted in the correct orientation regarding lordosis. It can be helpful to break the bed or inflate the lumbar pillow to get the disc implant started in a particularly collapsed disc. Once the implant is halfway into the disc space, the lordosis should be removed so that the implant will move easily into the posterior portion of the disc (TECH FIG 5E,F).

ANTERIOR LUMBAR CORPECTOMY

Vertebra Removal
- The indications for anterior corpectomy in the lumbar spine are lumbar burst fracture, catastrophic failure of lumbar disc replacement or interbody device (ie, vertebral fracture), lumbar vertebral osteomyelitis, correction of kyphosis, and vertebral body malignancy.
- In cases of corpectomy for vascular tumors, pre-operative embolization should be performed (TECH FIG 6A).
- In cases of corpectomy, lumbar radical discectomies are performed above and below the vertebral body to be removed (see discectomy technique above).
TECH FIG 6 • A. Pre-embolization angiogram depicting the aortic bifurcation in a 65-year-old patient with metastatic renal cell carcinoma to the L4 vertebra. Note the degree of vascularity of the L4 vertebral body. B. Postembolization angiogram depicting a striking reduction in contrast entering the L4 vertebral body. Small embolization coils are seen in the vascular network surrounding the vertebral body. C. Anterior disectomy enables the surgeon to use a large rongeur to gain access to the edge of the vertebra and thereby remove the vertebral body bone.

- This enables the surgeon to become oriented to the midline and also to judge the depth and width of the corpectomy to be performed.
- The discectomy space also allows the surgeon to use a large rongeur efficiently to remove the vertebral body (TECH FIG 6B).
- Retractors should be placed above and below the entire vertebra to be removed so there is an unobstructed view for the surgeon and the assistants. The vertebral body bleeds more rapidly than the endplates, so the assistants need to be able to visualize the operative field to suction effectively.
- A Leksell rongeur can be used to remove all of the vertebral body back to the level of the posterior cortex. If this needs to be removed, angled curettes are used to develop the plane behind the vertebra, starting at the disc space. Kerrison punches or angled curettes are then used to lift the posterior cortex off the ventral dura.
- Healthy vertebral body bone should be saved for interbody fusion.

Filling the Interbody Space

- Once the corpectomy is completed, bone graft or an interbody device is contoured to fit into the defect. The wooden end of a cotton-tipped applicator can be cut to the length of the defect and can then be used as a size gauge for the final interbody device. This is particularly useful when cutting and contouring a bone graft because calipers and rulers do not always fit easily into the central portion of the corpectomy defect to give an accurate height measurement.
- Check the height of the corpectomy defect with the wooden applicator throughout its entire depth, from anterior to posterior. Keep in mind that the shape of the corpectomy site may be lordotic, and thus the bone graft or implant needs to be fashioned appropriately.
- Allograft strut grafts such as femoral head, humerus, or femoral shafts can be cut using an oscillating saw to fit snugly into the interbody space. The advantages of allograft are it can be packed with morselized autogenous bone, it has a similar modulus of elasticity to host vertebral bone, and it will become osseointegrated over time. Autogenous tricortical iliac crest and autogenous fibula have the greatest healing potential but are also associated with significant harvest site morbidity.
- Metal cages generally are the easiest to fashion to fit the corpectomy space and can be packed with morselized corpectomy bone (TECH FIG 7A). The disadvantages are their expense and relatively reduced surface area at the endplate for fusion compared to bone.
- The width of the corpectomy should be kept as narrow as possible without compromising decompression or removal of pathologic bone (TECH FIG 7B).
- Allows bone ingrowth from the corpectomized vertebral body into the interbody bone graft.
- Enhances the stability of the interbody strut.
- A bone screw with a washer can be used above and below large defects as an “anti-kickout” buttress for allografts (TECH FIG 7C).
Chapter 17  ANTERIOR LUMBAR INTERBODY FUSION, DISC REPLACEMENT, AND CORPECTOMY 4643

TECH FIG 7 • A,B. AP and lateral postoperative radiographs of a patient in whom posterior element resection followed by fusion and instrumentation with pedicle screws was performed as a first stage, followed by complete anterior corpectomy and reconstruction with a cylindrical titanium mesh cage packed with autogenous bone graft. An anterior side plate was applied as the lateral vertebral body wall was completely removed. C. The corpectomy strut device should fit snugly against the cut edge of the vertebral body to promote side-to-side fusion from host bone to strut graft. D. Intraoperative image of anterior allograft reconstruction after corpectomy, irrigation, and débridement of the L3 vertebra in a 62-year-old man with L3 vertebral body destruction from pyogenic vertebral osteomyelitis. 4.5-mm cortical screws with washers are used to prevent allograft kickout.

PEARLS AND PITFALLS

Use of a pulse oximeter on the left great toe provides real-time feedback to the surgeon about perfusion to the distal extremity during great vessel retraction.

- There should be a low threshold for prophylactic inferior vena cava filter placement in patients with venous injuries requiring repair, as pulmonary embolism, although rare, carries potentially catastrophic consequences.

Perforation of the cancellous vertebral body endplates with Cobb curettes or the lamina spreader increases the likelihood of implant subsidence.

- Early (less than 2 weeks) implant malpositions or migrations can be easily revised as the anterior tissue planes are still preserved.

Epidural bleeding can be effectively controlled quickly with thrombin-soaked Gelfoam gauze and release of any disc space distractors.

- Overdistraction of the disc space with a lumbar disc replacement implant will result in compromised motion and may be associated with new postoperative leg pain related to stretch injury to the lumbosacral nerve trunks.

Marking the location of the dorsalis pedis and posterior tibial pulses with a marking pen facilitates reassessment of pulses in the postoperative setting when lower extremity swelling is more prevalent.
have significantly improved fusion rates and clinical outcomes compared to patients in whom the cages were packed with iliac crest bone graft.

In a prospective, randomized trial comparing Charite lumbar disc replacement to stand-alone anterior lumbar interbody fusion with titanium cages and iliac crest bone graft (control group), a significantly greater percentage of patients undergoing disc replacement were satisfied with their procedure versus the control group at 2-year follow-up.

- Hospital stay was significantly shorter in the disc replacement group compared to controls.
- However, at 2 years there was no statistical difference between the disc replacement group and the control group with respect to pain or disability.
- Clinical outcomes and flexion-extension range of motion correlate with surgical technical accuracy of lumbar disc replacement.

COMPLICATIONS
- Most complications associated with anterior lumbar discectomy, interbody fusion, disc replacement, and corpectomy are approach-related.
- The most common complications of anterior lumbar interbody fusion are pseudarthrosis and device failures such as migration or breakage.
- The complications of lumbar disc replacement depend on the exact type of device being inserted but generally can be categorized as follows:
- Device failures: metal endplate breakage, core dislodgement or fracture, polyethylene degradation
- Bone-implant failures: subsidence, vertebral body fracture, implant migration or dislocation
- Iatrogenic deformity: kyphosis, scoliosis
- Host response: osteolysis, heterotopic ossification
- Infection
- Revision approaches to the anterior lumbar spine carry six times the risk of major bleeding or thromboembolic complications. Preoperative intravenous filter insertion, ureteral stenting, and percutaneous venous access wires are critical to reduce these risks.

OUTCOMES
- Level IV evidence reported by Tropiano et al showed significant improvements in back pain, radiculopathy, and disability at mean of 8.7 years after insertion of the Prodisc lumbar disc replacement.
- Anterior lumbar interbody fusion with titanium cages and iliac crest bone graft has been shown to yield significantly greater fusion rates (97%) versus allograft dowels packed with iliac crest bone graft (48%).
- Patients undergoing anterior lumbar fusion with the titanium cages packed with BMP-2-impregnated collagen sponges have significantly improved fusion rates and clinical outcomes compared to patients in whom the cages were packed with iliac crest bone graft.

POSTOPERATIVE CARE
- As soon as the patient emerges from anesthesia, a complete neurologic examination and brief history should be performed. Specifically, patients should be asked if they have any new leg pain. If present, CT myelography or plain CT scans should be obtained to ensure that no bone, disc material, or portion of an implanted device is impinging on the lumbar nerve roots.
- Nasogastric tubes for the first 12 to 24 hours help to minimize abdominal wall distention and postoperative ileus.
- Patients are encouraged to walk on postoperative day 1.
- Lumbar corsets or abdominal binders are prescribed at the discretion of the surgeon and may reduce the tension on the abdominal incision in the early postoperative period.
- Return to heavy manual labor is restricted in patients undergoing anterior interbody fusion until the fusion is solid. Fine-cut CT scans are useful in documenting solid fusion if there is doubt on AP, lateral, or flexion-extension radiographs.
- Manual labor should be restricted in patients undergoing disc replacement until the bone–prosthesis interface is judged to be stable. In nonkneelded total disc replacement devices requiring porous ingrowth for definitive fixation, such as the Charite (DePuy Spine, Raynham, MA), at least weeks out of work is recommended.

COMPLICATIONS
- Most complications associated with anterior lumbar discectomy, interbody fusion, disc replacement, and corpectomy are approach-related.
- The most common complications of anterior lumbar interbody fusion are pseudarthrosis and device failures such as migration or breakage.
- The complications of lumbar disc replacement depend on the exact type of device being inserted but generally can be categorized as follows:
- Device failures: metal endplate breakage, core dislodgement or fracture, polyethylene degradation
- Bone-implant failures: subsidence, vertebral body fracture, implant migration or dislocation
- Iatrogenic deformity: kyphosis, scoliosis
- Host response: osteolysis, heterotopic ossification
- Infection
- Revision approaches to the anterior lumbar spine carry six times the risk of major bleeding or thromboembolic complications. Preoperative intravenous filter insertion, ureteral stenting, and percutaneous venous access wires are critical to reduce these risks.

REFERENCES

DEFINITION
- Adult scoliosis is a coronal deformity of the spine, typically also involving axial and sagittal plane abnormalities.
- Adult scoliosis may be categorized by patient presentation.
  - One group, predominantly defined by lumbar stenosis and neurogenic claudication with degenerative deformity, has surgical management typically achieved by posterior lumbar procedures.
  - A second group, categorized by progressive deformity, with or without back pain, is more frequently treated with combination anterior and posterior procedures that may involve the thoracic spine to achieve surgical goals.
- While the surgical principles and techniques used to address these different categories are similar, important variations exist.

ANATOMY
- Anatomic characterization of adult spinal deformity involves the coronal, sagittal, and axial planes.
  - Lumbar degenerative scoliosis is characterized by loss of lordosis and intervertebral disc height, as well as listhesis in the anteroposterior, lateral, or rotary direction (FIG 1A,B).
  - Long curves, typically the result of a preexisting spinal deformity, may involve the entire thoracolumbar spine and may be associated with a significant rotational component (FIG 1C,D).

PATHOGENESIS
- Adult scoliosis develops either as the progression of a spinal deformity that was present in adolescence, or as the development of a deformity related to other spinal disorders.
  - The progression of the adolescent spinal deformity is related to increasingly unbalanced forces in the axial skeleton over time.
  - De novo adult deformity is commonly the result of degenerative disease and may also be related to osteoporotic fragility fractures of the vertebrae, resulting in a deformity frequently associated with spinal stenosis and mechanical back pain.

NATURAL HISTORY
- The progression of an adolescent deformity is often seen as a long thoracolumbar curve in the adult.
  - Curves that reach a magnitude of more than 50 degrees are more likely to progress, resulting in symptom exacerbation.
  - As patient age increases, curve flexibility decreases.
  - Lumbar degenerative curves typically involve fewer segments and may be limited to the lumbar spine.
- Degeneration and deformity can cause central, lateral recess, and neural foraminal stenosis as a result of:
  - Loss of intervertebral height
  - Hypertrophy of facet joints
  - Buckling of the ligamentum flavum
  - Compression deformities
  - Neurogenic claudication, as well as radiculopathy and back pain, may result.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Determining the reason for the patient’s presentation is the first step in establishing the goals of surgical treatment.
- Patients with extensive thoracolumbar deformity may present with concerns related to curve progression with an impact on:
  - Balance
  - Ambulation
  - Pain
  - Cosmesis
- Patients with lumbar degenerative scoliosis classically present with complaints of neurogenic claudication.
  - Hip and knee flexion contractures, related to the typical forward-flexed ambulation that limits the symptoms of neurogenic claudication, may be found (FIG 2).
  - Major focal neurologic abnormalities are unusual in this patient group, although relatively mild degrees of weakness in the tibialis anterior and extensor hallucis longus are not uncommon.
- Physical examination should include the following:
  - Assessment of sagittal balance based on lateral observation of the patient standing with knees extended. A plumb line is dropped from the ear and the deviation (anterior or posterior shift) at the greater trochanter is measured, as is the regional (lumbar) lordosis and (thoracic) kyphosis. An upright posture with head over trunk and trunk over pelvis is a critical treatment goal.
  - Assessment of coronal balance based on posterior observation of the patient standing. A plumb line is dropped from the occiput and the deviation (leftward or rightward shift) at the sacrum is measured. A centered posture reduces gait abnormality.
  - The clinician should observe and palpate the vertical relationship of the right and left acromions with the patient standing. Shoulder asymmetry may indicate coronal postural compensation to maintain upright stance.
  - The clinician should observe and palpate the vertical relationship of the right and left iliac crests with the patient standing on the right, left, and both legs. Pelvic obliquity may be a primary or compensatory mechanism with spinal deformity.
  - Assessment of hip and knee range of motion. Longstanding sagittal plane deformities, as well as neurogenic claudication, may result in hip and knee flexion contractures.
  - Focal findings may be uncommon, but a thorough neurologic examination must be performed.
IMAGING AND OTHER DIAGNOSTIC STUDIES

Radiographs

- Standing posteroanterior (PA) radiographs on 36-inch cassettes characterize the spinal deformity by:
  - The magnitude of primary and compensatory curves, by the Cobb method (FIG 3)
  - Coronal balance: the relationship between the C7 plumb line and center of S1 on PA views (FIG 4)

- The apical vertebrae (most laterally deviated; FIG 5A)
- The stable vertebra (caudal vertebra that is transected by the z axis; FIG 5B)
- Rotary and lateral listhesis
- Standing lateral radiographs on 36-inch cassettes characterize the spinal deformity by:
  - Regional lordosis and kyphosis (FIG 6)
  - Sagittal balance; the relationship between the C7 plumb line and center of S1 on lateral views (FIG 7)
  - Anterolisthesis or retrolisthesis

FIG 1 • A,B. Degenerative lumbar scoliosis in PA (A) and lateral (B) radiographs. Lateral, rotary, and anterolisthesis are seen, with significant loss of disc height, osteophyte formation, and subchondral sclerosis. The coronal deformity is limited to the lumbar region. C,D. A long scoliosis involving the lumbar and thoracic regions, associated with rotational deformity, shown in PA (C) and lateral (D) radiographs.

FIG 2 • Neurogenic claudication is frequently associated with this gait abnormality. A forward-flexed posture may provide postural relief of posterior foraminal stenosis but typically alters the sagittal balance, as depicted here. Hip and knee flexion contractures may be associated.

FIG 3 • The Cobb method is used to measure the coronal deformity. Vertebral endplates (or the margins of pedicles) are used to extend lines as depicted for each of the curves involved. Lines orthogonal to these are then compared to determine the scoliosis angle. Vertebrae are typically selected to maximize the Cobb angle on each measurement.
Coronal balance is evaluated on the standing PA radiograph. A virtual plumb line is dropped from the center of C7. The lateral distance between that plumb line and the center of S1 is then measured. (Left to right) Negative coronal decompensation, coronal compensation, and positive coronal decompensation. CSVL, center sacral vertical line.

The apical vertebra is defined as that which is most deviated laterally on the PA radiograph. The stable vertebra is defined as the caudal vertebra that is transected by the vertical plumb line extending from the center of S1 on the standing PA radiograph. CSVL, center sacral vertical line.
Right- and left-bending PA radiographs (FIG 8) are used to:

- Evaluate spinal flexibility
- Determine the structural or nonstructural nature of the curve
- Supine traction radiographs may also be used to evaluate curve flexibility.

**CT Scans**

- Axial CT images, reformatted in the plane of the superior endplates of each vertebra, may be used to measure pedicle dimensions for preoperative planning.
- Plain radiographs and CT images can be used to assess the degree of bone loss and tailor the reconstructive techniques to the bone quality of the patient.

**MRI**

- MRI is used to assess neurologic compression (FIG 9) as well as the status of the disc, ligamentum flavum, and other soft tissues.

**Dual-Energy Radiographic Absorptiometry**

- Dual-energy radiographic absorptiometry (DEXA) is often performed for patients with identified risk factors:
  - History of fracture as an adult or fracture in a first-degree relative
Part 9 SPINE • Section III THORACOLUMBAR SPINE SURGERY

- White race
- Advanced age
- Smoking
- Low body weight
- Female gender
- Dementia
- Poor health or general fragility

Provocative Tests
- Discography can be useful to assess for painful segments, particularly in the lower lumbar spine.
- Facet blocks have been employed to determine levels that should be included, or need not be included, in the fusion. This may be particularly relevant at the lumbosacral junction.20

NONOPERATIVE MANAGEMENT
- A physical therapy regimen may be tried, focusing on:
  - Stretching and core-strengthening exercises
  - Postural training
  - Gait training
  - Resolution of hip and knee flexion contractures
  - General conditioning
- Nonsteroidal anti-inflammatory medications may be used if safely tolerated

SURGICAL MANAGEMENT
- The treatment of adult scoliosis is complex because of the global nature of the spinal deformity and the multiple causes of this disorder.
- Efficiency, safety, and effectiveness in meeting surgical goals are each optimized by a well-designed procedure.

Preoperative Planning
- Preoperative planning is instrumental to a successful treatment algorithm; avoiding both short- and long-term complications is paramount.
- In 1968, the complications associated with surgical correction of adult deformity were estimated to include:31:
  - 5% risk of death
  - 6% risk of major neurologic deficit
  - 20% risk of correction loss
  - 10% risk of deep infection
  - 40% risk of major medical complication

FIG 8 • Bending radiographs aid in determining the flexibility of the spinal curves and are also used to determine the structural or nonstructural nature of the curves.

FIG 9 • MRI is particularly useful in evaluating patients with neurologic symptoms such as claudication. It is used to assess neurologic compression as well as the status of the disc, ligamentum flavum, and other soft tissues.
With advances in surgical and anesthetic techniques, neurophysiologic monitoring, and improvements in perioperative management, these risks have been significantly decreased.

The patient with adult scoliosis may carry a myriad of co-morbidities that may increase the risk of a spinal operation or even contraindicate it. A complete preoperative assessment of those considering surgical treatment provides the opportunity to minimize risks by optimizing health status.

Modifiable conditions that affect surgical risk include:
- Tobacco smoking
- History of asthma or chronic obstructive pulmonary disease
- Coronary or cerebrovascular disease
- Diabetes
- Nutritional deficiency
- Osteoporosis
- Depression
- Current significant life stressors

Collaboration with consulting medical specialists who are trained in perioperative management is an important technique to optimize outcomes for patients with adult scoliosis.

Anesthesia colleagues familiar with this surgical course may also reduce risks.

Certain medical considerations directly affect the selection of surgical techniques for a patient with adult scoliosis.
- Assessment of bone quality plays a critical role in the design of the operation.
- Osteoporosis is the rule, not the exception.

**Approach**

Posterior surgical approaches are typically used for the treatment of adult deformity correction.

Anterior surgery may be used alone in isolated cases but is more frequently combined with posterior surgery to augment the deformity correction, reconstruction, or both.

Anterior exposure allows the soft tissue releases that are often required for adequate deformity correction.

**General Procedures**

**Fixation Strategies for Osteoporotic Bone**

- Spinal instrumentation with pedicle screw fixation is less effective in osteoporotic bone.
- Trabecular bone is predominantly affected by osteoporosis.
- Since pedicle screws have cortical contact limited to the pedicle isthmus, a “windshield wiper” mode of failure typically leads to screw loosening.
- Fixation strategies for osteoporotic bone are targeted toward:
  - Taking advantage of the relatively stronger cortical bone
  - Augmenting the fixation of a pedicle screw within the existing trabecular bone
- Bone-implant interface complications in the osteoporotic spine can be reduced by various methods.
  - Sublaminar wires and pediculolaminar fixation take advantage of the cortical bone composition of the posterior spinal lamina (FIG 10).
  - Fixation of pedicle screws within osteoporotic trabecular bone may be improved by polymethylmethacrylate (PMMA) cement augmentation.
    - Fluoroscopy is used to visualize the placement of 2 to 3 cc of PMMA per pedicle to ensure that cement does not migrate to the neural elements.

**Fusion and Bone Grafting**

- Establishment of a solid fusion is critical.
- The pseudarthrosis rate in one large series of adult deformity patients after long fusion procedures was 24%.
- Statistically significant risk factors for pseudarthrosis in that study included:
  - Thoracolumbar kyphosis
  - Hip osteoarthritis
  - Use of a thoracoabdominal (versus paramedian) approach
  - Positive sagittal balance greater than 5 cm
  - Age greater than 55 years
  - Incomplete sacropelvic fixation

These risk factors emphasize the importance of surgically establishing the proper mechanical environment, including overall sagittal balance and appropriate fixation.

**Bone Graft Selection**

- Appropriate graft selection may reduce pseudarthrosis risk.
- Bone grafts and alternatives may serve multiple roles in the surgical treatment of adult scoliosis; fusion-promotion and deformity-correction techniques both may influence graft selection.

**Calcium sulfate paste may also be used; this has the theoretical advantage of becoming replaced by bone over time.**

- Modified pedicle screws may also be used, including conical screws, hydroxyapatite-coated screws, and expandable screws.

**PEDICLE SCREW ELECTION AND PLACEMENT**

- Screw pullout strength is improved when high insertional torque is achieved:
  - Undertapping (or not tapping) the screw path
  - Using tapered screws. These are limited by the absolute restriction that they cannot be reversed or backed out; such an action would remove the screw’s contact with the bone.
  - Using larger-diameter screws. Increased cortical contact may increase insertional torque but may increase the risk of pedicle fracture as well.
  - Using longer screws: Bicortical purchase can increase screw pullout strength but may pose the possibility of injury to abdominal or vascular structures.

**FIG 10 • Fixation strategies for osteoporotic bone may include the use of multiple fixation points in a vertebra. Such instrumentation, as depicted here, incorporates pedicle screw and laminar hook instrumentation at the same vertebral level.**
An anterior interbody graft may need to be structural to correct a deformity.

- If a structural graft is used anteriorly first, it is with the anticipation that further deformity correction at that segment will be limited by posterior manipulation.
- Anterior structural interbody grafts can be instrumental in preventing a kyphosis when the convexity of a deformity is compressed in a reduction maneuver.
- Structural grafts can be placed with a bias toward the concavity in order to assist in the deformity correction.
- Structural interbody grafts serve a critical role in supplementing the stability of a reconstruction, particularly at the caudal end of a construct, at the lumbar–sacral junction.
- Morselized grafts may allow for deformity correction by subsequent posterior manipulation.

Our typical strategy is as follows:

- Use structural grafts at the caudal end of the construct (two to four levels).
- Overzealous posterior manipulation can cause loosening or displacement of an anterior structural graft.
- Use morselized graft rostrally.
- Subsequent deformity correction during the posterior procedure will be limited mainly to those levels with morselized (or no) anterior graft.

**INTERBODY GRAFT MATERIALS**

- Graft selection is guided by:
  - The goal of fusion success
  - The potential utility of structural roles for the graft
  - The risk of potential complications and other shortcomings
  - Costs
- Interbody grafts may be composed of:
  - Bone (autograft or allograft)
  - Metal
  - Carbon fiber
  - PEEK
  - Other synthetic material
- To reduce the risk of graft subsidence, a graft with a modulus of elasticity similar to that of the native bone can be employed.
  - Iliac crest autograft is typically the best modulus match but is associated with well-established harvest-related morbidity.
  - In osteoporosis, we have used allograft harvested from the iliac crest of a donor, which offers:
    - A relatively high proportion of trabecular to cortical bone compared to a long bone allograft, and an improved modulus match
    - More rapid biologic incorporation of trabecular grafts
  - Carbon fiber and PEEK interbody cages offer a lower (and more closely matched) modulus compared to metal cages; we typically avoid metal cages in the reconstruction of osteoporotic spinal deformities.
- Autograft remains the gold standard material for establishing a solid arthrodesis but has shortcomings:
  - Morbidity of iliac crest autograft harvest
  - Chronic donor-site pain
  - Postoperative hematoma, infection
  - Nerve or vessel injury
  - Iliac graft harvest may be undesirable when iliac instrumentation is planned.
- Autograft may be insufficient for an extensive thoracolumbar fusion.
- Autograft alternatives include allograft products, synthetics, and bone morphogenetic proteins (BMP).
- The fusion efficacy of BMP-2 has recently been demonstrated in patients with adult spinal deformity.
- Seventy adult patients underwent scoliosis fusion with anterior or posterior BMP-2 application, with either local bone graft only (posterior) or no bone graft (anterior), obviating rib, iliac crest, or other autograft harvest morbidity.
- Fusion rates were satisfactory, with 96% anterior fusion success and 93% posterior fusion success.

**BONE MORPHOGENETIC PROTEIN**

- Attention to certain surgical techniques reduces the risk of complications and may also improve efficacy.
- The risks associated with the use of BMP in the cervical spine include:
  - Complications related to soft tissue swelling
  - Inappropriate bone formation
  - Accelerated graft resorption
- In the lumbar spine, there also have been reports of undesirable effects, including:
  - Inappropriate bone formation around neural elements
  - Postoperative radiculitis
  - Accelerated resorption of interbody grafts, increasing the risk of pseudarthrosis, has also been reported in a study of single-level uninstrumented anterior lumbar interbody fusion.
- Structural allograft with appropriate doses of BMP at the lower two to four levels in adult thoracolumbar fusions can, however, be used with minimal risks of complications.
- Example: BMP-augmented transforaminal lumbar interbody fusion (TLIF)
  - Care is taken to reduce the risk of inappropriate bone formation.
  - These steps may help ensure maintenance of the BMP and limit the BMP from affecting adjacent tissues:
    - Irrigate before the placement of the BMP packed cage, not afterward.
    - Pack the BMP sponge entirely within the cage, avoiding “overstuffing.”
    - Place additional sponge only anterior to the cage.
    - Use a repairable “trapdoor” annulotomy.
  - A three-sided annular flap is created, hinging medially, such that when the flap is held open with sutures at its corners, it augments the protection of the thecal sac.
  - After discectomy and placement of BMP, anterior graft, and TLIF cage, the annulotomy is repaired with suture and augmentation of the closure with an adjuvant sealant.

**Sagittal Balance**

- The single most important principle in the surgical treatment of adult scoliosis is achieving and maintaining a proper sagittal balance.
- Balanced spinal posture with neutral positioning:
  - Provides for decreased energy requirements with ambulation
  - Limits pain and fatigue
  - Improves cosmesis and patient satisfaction
  - Limits complications associated with unresolved (or new) deformities
FUSION LEVEL SELECTION

- Sagittal balance must be achieved.
- Functional problems must be avoided.
- Presenting symptoms can guide level selection.
  - Discography can be useful to assess for painful segments, particularly in the lower lumbar spine, that may be incorporated in the fusion.
  - Facet blocks have been employed to determine levels that should be included or need not be included. This may be particularly relevant at the lumbosacral junction.20

RODRIGUETHI

- 36-inch standing PA and lateral
- PA (left and right) bending views, to determine if the main curves are structural
  - If the Cobb angle is greater than 25 degrees on side-bending radiographs, then it is considered to be a structural curve.25
  - Curve magnitude and flexibility and the apical vertebral translation of the thoracic and lumbar curves are measured.
  - The relationship between the C7 plumb line and the center sacral vertical line is considered.
  - Radiographic signs of degenerative disease are categorized.
  - Listhesis (rotary and lateral) are noted. Degenerative segments often are associated with stenosis; this must be considered in the treatment algorithm.

FUSION TO THE SACRUM

- Extension of the fusion to the sacrum for the adult scoliosis patient is an important and controversial subject. There is no consensus as to the best strategy for all clinical scenarios, but certain guidelines and lessons have been developed.
  - There is a relatively high rate of pseudarthrosis (and other complications) after L5–S1 fusion.11,19 For these reasons, in part, some have advocated avoiding fusion to the sacrum whenever possible.3
  - Certain scenarios do require lumbosacral fusion:
    - Symptomatic L5–S1 spondylolisthesis
    - Other instability
    - Oblique take-off with over 15 degrees of scoliosis at the L5–S1 segment often requires reduction and fusion for adequate correction of deformity.
    - For correction of lumbar hypolordosis to achieve proper sagittal balance
  - The risk of pseudarthrosis at the lumbosacral junction can be limited by:
    - Employing combined approaches to perform a meticulous 360-degree fusion at the L5–S1 segment
    - BMP may be applied to further increase the chances of solid arthrodesis.
    - Anterior instrumentation has been advocated:
      - Fixed-angle plates
      - Vertebral body compression screws
      - Isolated posterior instrumentation may be satisfactory if good bicortical purchase is achieved with sacral screws, with high insertion torque.
    - Additional fixation is required, however, in many cases, and iliac screws or Galveston technique fixation satisfies this need.
  - Recently, the use of allograft with BMP and posterior pedicle fixation, without iliac fixation, has been used successfully due to the speed of healing, with the caveat that this depends on the length of fusion.

Specific Management Strategies by Diagnosis

Degenerative Lumbar Scoliosis

- The patient with adult lumbar scoliosis typically has some component of back pain and may also present with radiculopathy or claudication.
- For the typical patient presenting with stenosis complaints, decompression of the neural elements is a priority.
- Deformity correction with proper sagittal balance also is a critical goal of surgery.
  - Loss of lumbar lordosis is associated with increased pain.37
  - Restoration of proper sagittal balance is the most important factor associated with clinical outcome.13
- The typical patient presents with hypolordosis and varying degrees of scoliosis, typically associated with relatively flexible thoracic compensatory curves less than 30 degrees or no thoracic curve (FIG 11A,B).
  - Common radiographic findings include:
    - Degenerative disease, most commonly at L5–S1
    - Rotatory subluxation at L3–L4 (FIG 11C,D)
    - Obliquity at L4–L5 (FIG 11E,F)
  - The choice of surgical approach for the treatment of lumbar adult scoliosis depends on:
    - The levels of the pain-generating segments
    - The flexibility of the curve
    - The coronal obliquity of the distal vertebrae
    - The extent of the curve
  - While in situ fusion may be an option for patients with small-magnitude deformity and poor bone quality, typically restoration of lordosis and coronal realignment are desired (FIG 12). This can be accomplished with a variety of methods, many of which require restoration of anterior height.

TLIF for Deformity Correction and Reconstruction

- TLIF may achieve these goals with a posterior-only approach.
- To assist in correction of the deformity, the cage may be biased to the concavity of the scoliosis to address the coronal plane.
- After facetectomy and posterior compression, lordosis can be restored.
  - In general, a posterior interbody technique (posterior or thoracic lumbar interbody fusion) is less effective than an anterior interbody approach for restoring lordosis.
  - The use of an operating table that produces extension of the lumbar spine (Jackson) to maximize positional lordosis is critical.
- The decision of the levels to include in the treatment of a degenerative lumbar deformity may be determined by a variety of influences.
  - It can be useful to preoperatively determine which segments contribute to a patient’s pain.
  - The apex of the deformity is included (typically L3 or L4).
  - Levels that are severely degenerated may also be included, particularly if they exhibit lateral or rotary listhesis.
- There is no general consensus as to where a lumbar construct should terminate cranially, but it should be at least at a stable end vertebra (ie, the cranial-end level of the fusion construct should be bisected by the center sacral line on a lateral radiograph).
- If the goal is to treat neurogenic claudication, relieve stenosis, and prevent future progression, a short-segment construct (often L2–L5) is sufficient if adequate lordosis is attained and the cranial and caudal vertebralae are well balanced.
In many scenarios, however, such as when the Cobb angle is from L1 to L5, it is necessary to continue the fusion cranially past the thoracolumbar junction. When this is the case, one should take care not to end the fusion at the thoracolumbar junction or at the apex of the thoracic kyphosis.

Extending the fusion to the thoracolumbar junction provides fixation into the more stable rib-bearing vertebrae and is more likely to terminate within the sagittal plumb line, reducing the risk of instrumentation failure or junctional kyphosis. A frequent decision-making dilemma is where to end the caudal end of the fusion reconstruction.

FIG 11 • A, B. Radiographs of a patient with degenerative lumbar scoliosis. Rotatory and lateral listheses are seen on the PA view (A) and the typical hypolordosis is seen on the lateral view (B) preoperatively. C, D. Lumbar radiographs of a typical patient with degenerative scoliosis limited to the lumbar region. The lateral listhesis is seen at L3–L4 (C) as well as the typical loss of lumbar lordosis (D). In another patient, obliquity at L4–L5 is seen in the preoperative PA radiograph (E), with focal loss of disc and neuroforaminal height seen on the preoperative lateral radiograph (F).

FIG 12 • A, B. After decompression of the patient in Figure 11A,B, spinal reconstruction is achieved with recreation of coronal (A) and sagittal (B) balance. C, D. In the patient in Figure 11E,F, postoperative reconstruction after decompression of the neural elements recreates lumbar lordosis to achieve proper sagittal balance.
Accepted indications to fuse to the sacrum include:
- Spondylolisthesis or previous laminectomy at L5–S1 (FIG 13A)
- Stenosis requiring decompression at L5–S1
- Severe degeneration
- An oblique take-off (above 15 degrees) of L5 (FIG 13B)

Fusions to the sacrum in adults with lumbar scoliosis have been found to:
- Require more additional surgery than those to L5
- Have more postoperative complications
- On the other hand, fusions to L5 have been associated with:
  - A 61% rate of adjacent segment disease
  - An associated shift in sagittal balance
- When fusion to the sacrum is performed, iliac fixation should be considered, particularly if the fusion includes more than three levels (FIG 13C,D).
- Augmentation of the lumbosacral reconstruction with interbody fusion at L5–S1:
  - Improves biomechanical stability
  - Reduces the risk of lumbosacral pseudarthrosis
- A structural graft at L5–S1 can:
  - Recreate lordosis, partially restoring sagittal balance
  - Diminish stenosis by restoring intervertebral height
- Hip and knee flexion contractures can be common in this group, with patients accustomed to ambulating with flexed posture.
  - A flexion contracture at the hip limits the patient’s ability to extend the sagittal plumb line posterior to the hips.
  - It may be necessary to address the patient’s hip pathologies before planning any surgical correction of a spinal deformity.

Thoracic and Lumbar (Double-Curve) Scoliosis
- Patients with double major adult scoliosis may present with axial skeletal pain.
- Complaints of progressive deformity may be manifested as:
  - Changes in balance
  - Gait abnormalities
  - Alterations in cosmesis
- The surgical treatment of double-curve scoliosis often combines anterior and posterior procedures (FIG 14).
  - Long deformities that are relatively inflexible may require anterior releases to accomplish effective reduction and fusion with posterior surgery.
  - In part because of the typical degeneration in adult patients, fusions into the caudal lumbar spine are more frequently required.
  - Bending films determine whether the lumbar flexibility is adequate for the scoliosis to “bend out” (see Fig 8).
    - Curve stiffness is related to both patient age and curve magnitude.
    - Flexibility decreases by 10% with every 10-degree increase in coronal deformity beyond 40 degrees.
    - Flexibility decreases by 5% to 10% with each decade of life.
- The correction of a double-curve deformity can be accomplished with a variety of methods. The primary goal of achieving a proper sagittal balance must be emphasized. Reduction of the coronal and rotational deformities follows in priority, with the goal of establishing coronal balance and reduction of rib asymmetry for enhanced cosmesis and patient satisfaction, if possible.
Analogous to the design of the operation for adult lumbar deformities, the decision of whether to extend the fusion to the sacrum may be difficult.

Lumbosacral fusion is recommended when:

- Decompression of L5–S1 stenosis is required
- There is a fixed obliquity over 15 degrees at L5–S1 (see Fig 13B)
- Long fusions to the sacrum increase the risk of pseudarthrosis and reoperation. These may be minimized by anterior augmentation and iliac fixation, as previously discussed (see Fig 14).
- The cranial end of the fusion should include the thoracic curve and should not stop caudal to any structural aspect of it.
- All fixed deformities and subluxations should be included in the fusion.

Rod cross-links increase the stiffness of long constructs and are recommended (see Fig 14C). They should be avoided at the thoracolumbar junction; however, where they may increase the risk of pseudarthrosis.

Vertebral derotation

Curve stiffness may limit the surgeon’s ability to reduce the rotational deformity in the adult population.

For relatively flexible rotational deformities, rotational reduction can be achieved with effective improvement in trunk symmetry, which can significantly improve patient satisfaction (Fig 15).

Additional release maneuvers may be necessary in stiff curves, including thoracoplasty, concave rib osteotomies, and aggressive facetectomies.

PEARLS AND PITFALLS

**Reduction of complications associated with BMP**

- The surgeon should minimize the dose of BMP specific to each application.
- The surgeon should minimize diffusion of the protein from the site of desired action.
- Meticulous hemostasis should be achieved before BMP implantation; a postoperative hematoma may provide an avenue for the spread of the protein.
- Wound irrigation should be performed before BMP implantation, not afterward.
- The BMP should be contained within a rigid structure to limit compression of the implant, to prevent pressure-induced diffusion.
- A barrier should be created between the protein implant and sensitive tissues. Thrombin glue has been used to seal the epidural space from the BMP.
- Hemostatic sponges and suction drains may permit protein to migrate to adjacent tissues and should not be placed adjacent to the protein implant.

**Prevention of adjacent-segment disease**

- The preoperative status (or health) of the segment or disc is the greatest predictor for the development of adjacent segment disease.
- For the population with adult scoliosis, where some identifiable degenerative disease is nearly ubiquitous, this is particularly relevant.
- The surgeon should not end a fusion adjacent to a severely degenerated disc.
- The surgeon should not end a fusion adjacent to a segment with fixed obliquity or subluxation.
- The surgeon should preserve the supra-adjacent facet.
- The surgeon should preserve the intraspinous and the supraspinous ligaments.
- The surgeon should not violate the cranial disc space with pedicle screws.
POSTOPERATIVE CARE

- If a brace is used, it must be custom-molded postoperatively, after surgical deformity correction is accomplished.
- Application of a preoperatively molded brace is counterproductive and should be avoided.
- Postoperative physical therapy regimen should focus on:
  - Range-of-motion and flexibility improvement, often in response to chronic hip and knee loss of motion or contractures
  - Gait training, to include balance rehabilitation
  - General conditioning

REFERENCES

DEFINITION
- The use of autogenous bone graft is considered by most surgeons to be the gold standard for achieving fusion in the spine.
- Autogenous bone graft can be used at any spinal level, anterior or posterior.
- The posterior ilium is most frequently harvested for non-structural, cancellous bone graft.
- Tricortical, structural bone grafts for cervical interbody fusions are typically harvested from the anterior ilium.

ANATOMY
- Anterior ilium
  - The anterior ilium has a concave anterosuperior surface.
  - The anterior iliac crest becomes its thickest (iliac tubercle) 2 to 3 cm posterior to the anterior superior iliac spine (ASIS) (FIG 1A).
- The lateral femoral cutaneous nerve typically courses medial to the ASIS; however, it can infrequently cross lateral to the ASIS and be at risk for injury (FIG 1B).
- Posterior ilium
  - The posterior iliac crest thickness ranges from 14 to 17 mm.
  - The superior cluneal nerve passes over the iliac crest 7 to 8 cm lateral to the posterior superior iliac spine (PSIS) and is at risk for injury with a lateral incision (FIG 1C).
  - The superior gluteal artery exits from the greater sciatic foramen (FIG 1D).

SURGICAL MANAGEMENT
Positioning
- A roll or bump of towels or a blanket beneath the ipsilateral ischial tuberosity can facilitate access to the anterior iliac crest.

FIG 1 • A. Ideal anterior iliac crest bone graft is obtained 2 to 3 cm posterior to the anterior superior iliac spine. B. The lateral femoral cutaneous nerve generally traverses medial to the anterior superior iliac spine. C. The superior cluneal nerves cross the posterior iliac crest 8 cm anterior to the posterior superior iliac spine. D. The superior gluteal artery exits from the greater sciatic foramen.
SURGICAL APPROACH

Anterior Iliac Crest
- A skin incision is made parallel to the iliac crest and is centered over the iliac tubercle.
- The incision is carried down to the bone of the crest and the muscles are elevated subperiosteally to expose the wing of the ilium (TECH FIG 1).
  - The tensor fascia latae, gluteus medius, and gluteus minimus originate from the lateral aspect of the ilium. These muscles are innervated by the superior gluteal nerve.
  - The abdominal muscles are also attached to the iliac crest and are segmentally innervated. The incision over the crest is, therefore, internervous and safe.

Posterior Iliac Crest
- The posterior superior iliac crest is palpable under the skin dimple in the superomedial aspect of the gluteal region.
  - A vertical incision over the PSIS is made to minimize injury to the cluneal nerves.
  - An oblique or curved incision may be made over the posterior iliac crest. The cluneal nerves cross the iliac crest 7 to 12 cm anterolateral to the PSIS; therefore, the incision should be made medial to this cutaneous innervation.
  - The subcutaneous tissue is divided to the level of the iliac crest.
  - Using Bovie cautery, the iliac crest is incised.
  - The muscles are elevated subperiosteally from the posterolateral surface of the ilium.
  - The gluteus maximus, medius, and minimus originate from the lateral surface of the ilium. The superior gluteal nerve innervates the gluteus medius and minimus and the inferior gluteal nerve innervates the gluteus maximus.
  - The paraspinal musculature is innervated segmentally.

Posterior Iliac Crest: Midline Skin Incision
- A midline spine incision may be extended distally and the posterior iliac crest approached laterally under the skin and subcutaneous fat. This avoids the use of a second skin incision.
- The fascia overlying the PSIS is incised on the medial surface, where it is more robust; this facilitates fascial closure upon completion of the bone graft harvesting.
- The PSIS is exposed on its outer surface with the aid of electrocautery via a subperiosteal dissection.

ANTERIOR TRICORTICAL ILIAC CREST BONE GRAFT
- After exposure of the anterior iliac crest, an oscillating saw can be used to make parallel cuts through the inner and outer table (TECH FIG 2A).
- Curved osteotomes can be used to make longitudinal cuts in the inner and outer tables to complete the tricortical bone graft harvesting (TECH FIG 2B,C).
POSTERIOR ILIAC CREST BONE GRAFT

Corticocancellous Strips

- After exposure of the posterior iliac crest, adequate visualization can be obtained with the use of a Taylor retractor.
- Caution should be taken to avoid penetrating the sciatic notch and potentially injuring the superior gluteal artery.
- The removal of bone in the vicinity of the sciatic notch can weaken the thick bone that forms the notch, resulting in pelvic instability.
- It is important to stay cephalad to the sciatic notch and remove bone only from the false pelvis. The false or greater pelvis is the portion of pelvis that lies cephalad to the pelvic brim, which defines the inner diameter of the pelvis.
- For a landmark, an imaginary line dropped anteriorly from the PSIS with the patient in the prone position can be used as the caudal limit of bone removal (TECH FIG 3A).
- Using a straight osteotome, multiple corticocancellous vertical strips can be cut from the iliac crest edge. A curved osteotome can be used to complete the cuts distally (TECH FIG 3B,C).
- After removal of the corticocancellous strips, gouges or curettes can be used to harvest additional cancellous bone (TECH FIG 3D).

Uncapping the Posterior Superior Iliac Spine

- With a rongeur, an osteotome, or both, the cap of the PSIS can be removed, allowing for harvesting of the cancellous bone between the two tables (TECH FIG 4A).
- Using a curette or gouge, the cancellous graft is then harvested through this window (TECH FIG 4B).

**TECH FIG 3** • A. Line directed anteriorly from the posterior superior iliac spine marks the caudal safe zone for bone grafting to avoid injury to the contents of the sciatic notch. B,C. Using osteotomes, several corticocancellous strips can be created from the posterior iliac crest. D. The void left after posterior bone graft harvesting.
Several graft site techniques have been described to improve cosmesis and function and to potentially reduce the onset of chronic dysesthesias.

Malleable bone cement contoured to the void can be used, particularly when structural bone graft has been harvested (TECH FIG 5A).

Crushed allograft bone chips can also be packed into the ilium between the inner and outer table, allowing for bone reconstitution.

After filling the defect with allograft or demineralized bone matrix, malleable polymerized lactide sheets can be contoured to the defect to allow for reconstitution of the external iliac anatomy (TECH FIG 5B).

**TECH FIG 4 •** A. The cap of the posterior superior iliac spine can be removed to expose cancellous bone. B. After removal of the cap of the posterior superior iliac spine, cancellous bone is exposed for harvesting (arrow).

**TECH FIG 5 •** A. After bone graft harvest, cement can be molded to fit the void left from the harvest. B. A mesh sheet can be used to traverse the bone graft void to restore the crest.
PEARLS AND PITFALLS

| Posterior iliac crest exposure | Preservation of the outer table spares the nociceptors located in the posterior perios- teum. Also, preserving the most distal portion of the iliac crest can allow for placement of iliac screws ipsilateral to the site of harvest if desired. |
| Lateral femoral cutaneous nerve | The lateral femoral cutaneous nerve passes 2 to 3 cm medial to the anterior superior iliac spine. Avoiding this area can minimize the risk of injury and meralgia paresthetica. |
| Superior cluneal nerves | The superior cluneal nerves cross the posterior cortex 8 cm lateral to the posterior iliac spine. Injury to these nerves can cause numbness to the posterior buttocks and occasion- ally painful neuromas. Vertical incisions are preferred. |
| Superior gluteal artery | Special care should be taken when working near the sacral notch. The superior gluteal artery exits the sacral notch and can be injured if graft is taken too close to the notch. If injured, this vessel may retract into the pelvis and cause significant hemorrhage. |

COMPLICATIONS

- Donor site pain is common after bone graft harvesting.
  - Most symptoms resolve within 3 months.
  - Chronic donor site pain persists beyond 3 months and can be debilitating.
- Anteriorly, nerves at risk for injury include the lateral femoral cutaneous, ilioinguinal, and iliohypogastric.
  - Injury to the lateral femoral cutaneous nerve may give rise to meralgia paresthetica (paresthesias along the lateral thigh). The ilioinguinal nerve may be injured when the abdomi- nal wall is retracted medially from the anterior iliac crest. The nerve may be compressed beneath the retractor on the inner part of the wall of the ilium. Ilioinguinal neurologic in- jury is characterized by pain radiating from the iliac toward the inguinal and genital areas.
- Posteriorly, nerves at risk for injury include the cluneal, su- perior gluteal, and sciatic.
  - The sciatic nerve may be injured when the dissection is ex- tended down to the sciatic notch. A surgical instrument such as an osteotome may be passed deep to the sciatic notch to cause this injury. The bony rim of the notch should be pallated before the dissection is carried to this area.
  - Injury to the cluneal nerves gives rise to numbness to the buttocks or, more rarely, painful cluneal neuromas.
  - Injury to the superior gluteal artery is rare but may occur with bone graft harvesting too close to the sciatic notch, or via inappropriate placement of retractors or elevators.
- If cut, the superior gluteal artery may retract into the pelvis.
  - If the superior gluteal vessel is lacerated, it can be com- pressed locally and exposed for ligation or clipping. A finger may be used to apply direct pressure to the vessel, against the bone.
  - If the bleeding vessel is still not accessible, the area should be packed and then accessed anteriorly via a retroperitoneal or transperitoneal approach.
  - Arterial occlusion by embolization or by use of a Fogerty catheter is another option.
- The deep circumflex iliac artery, the iliolumbar artery, or the fourth lumbar artery may cause troublesome bleeding when working on the inner table of the ilium.
- A hernia through the iliac bone graft donor site may occur after the removal of a full-thickness bone graft from that site. Symptoms may appear as an iliac swelling, sometimes associated with pain or symptoms of bowel obstruction. Strangulated hernia and valvulae are very rare occurrences.
- Fracture
  - Removal of a large quantity of bone graft from the poste- rior ilium may disrupt the mechanical keystone effect of the sacroiliac joint and the posterior sacroiliac ligament, causing instability.
  - The ensuing instability transfers the stress forces to the pelvic ring, causing fractures of the superior and inferior pubic rami.
  - Patients with such instability may develop symptoms indistinguishable from other spinal disorders. History of clicking or thudding, as well as pain in the thigh and gluteal re- gion, is characteristic.
  - Anteriorly, bone resection less than 3 cm from the ASIS may result in an avulsion fracture of the ASIS from the at- tached muscle groups (sartorius, tensor fascia lata).
  - The incidence of infection of the bone graft site ranges from 1% to 5%.
- Careful subperiosteal dissection can limit hematoma for- mation. Hemostasis after bone graft harvesting with clotting agents (Gelfoam) should be used to limit hematoma formation.
- The harvesting of tricortical grafts, particularly in thin pa- tients, can result in a cosmetic deformity. Careful closure of fascial attachments should be performed to minimize soft tis- sue defects.

surgical management of, 944, 944f
techniques for, 944–947, 945f, 946f, 947f
with femoral bone loss, distal femoral
replacement, 962–968
anatomy and, 962
bone cement for, 964, 964f
bulk allograft replacement, 966–967, 966f, 967f
bulk femoral head reconstruction and, 965, 965f, 966f
complications of, 968
definition of, 962
diagnostic studies for, 962–963
differential diagnosis of, 963
femoral component in, 964, 965f
imaging for, 962–963
metal augment for, 964, 965f
morselized allograft for, 964, 964f
natural history of, 962
nonoperative management of, 963
outcomes of, 968
pathogenesis of, 962
patient history and, 962
pools and pitfalls of, 967–968
physical findings and, 962
postoperative care of, 968
surgical management of, 963–964
tumor reconstruction prosthesis for, 967
with removal of well-fixed components,
975–977
anatomy and, 975
complications of, 979
definition of, 975
diagnostic studies for, 975
differential diagnosis of, 975
exposure and, 976
femoral component removal and,
977–978
imaging for, 975
nonoperative management of, 975
patella component removal and, 972f, 978
pathogenesis of, 975
patient history and, 975
pools and pitfalls of, 979
physical findings and, 975
stemmed implant removal and, 979
surgical management of, 976, 976f
tibial component polyethylene removal and,
976, 977f
tibial component removal and, 977, 977f
stiffness correction with, 994–1003
anatomy and, 994, 994f
closure and, 1001, 1002f
complications of, 1003
component removal and, 999, 999f
definition of, 994
diagnostic studies and, 995–996
physical findings and, 995
femoral trial size/augments and,
choosing, 1000–1001, 1001f
imaging and, 995–996, 996f
natural history of, 995
nonoperative management of, 996
outcomes of, 1002, 1003
parapatellar arthroscopy, medial with
complete intra-articular release and,
997–998, 998f
pathogenesis of, 994–995
patient history and, 995
pools and pitfalls of, 1002
physical findings of, 995
postoperative care of, 1002
quadriceps snip and, 998, 999f
surgical management of, 996–997, 997f
thibal platform for, creating, 1000, 1000f
tibial resection and posterior release in,
999, 1000f
trialing and, 1001, 1002f
with tibial bone loss, bone grafting for,
969–974
anatomy and, 969
complications of, 974
definition of, 969
diagnostic studies for, 969
differential diagnosis of, 969–970
imaging of, 969, 970f
impaction grafting and, 971, 971f, 972f
natural history and, 969
nonoperative management of, 970
outcomes of, 974
pathogenesis and, 969
patient history and, 969
pools and pitfalls of, 973
physical findings for, 969
postoperative care of, 974
structural femoral head allograft and,
972, 973f
surgical management of, 970, 970f
with tibial bone loss, metal augment for
anatomy of, 949–950, 950f
approach to, 953, 954f
block or step augment, medial/lateral and,
956, 956f
complications of, 960–961
component explanation and, 954
definition of, 949
diagnostic studies for, 952
differential diagnosis of, 953
full-width wedge augment and, 956, 956f
hemil wedge augment, medial/lateral and,
954, 955f
imaging for, 952, 952f
metaphyseal cone augmentation and,
957–958, 957f
natural history of, 951–952
nonoperative management of, 953
outcomes of, 960
pathogenesis of, 950–951
patient history and, 952
pools and pitfalls of, 959
physical findings and, 952
postoperative care for, 960
surgical management of, 953
techniques for, 953–959, 954f, 955f,
956f, 957f, 958f, 959f
trabecular metal augmentation, free and,
958, 958f, 959f
Rheumatoid arthritis (RA)
definition, 2608, 3420
diagnostic studies, 3420–3422, 3421f
differential diagnosis, 3422
forefoot, 3736
diagnostic studies for, 3736
differential diagnosis of, 3736–3737
imaging of, 3736, 3737f

pathogenesis, 2865, 2865f, 2865f
patient history, 2865–2866
physical findings, 2865–2866
surgical management, 2867–2868

Ulner metadiaphyseal fractures
anatomy and, 2224, 2225f
ORIF, 2224–2232

Ulner neck fractures
distal, ORIF for, 2232, 2232f
surgical management, 2228–2229, 2228f
Ulnar nerve

- anatomy, 2716, 3053
- resection, 1810–1811
- exposing, elbow contracture release and, extrinsic, 3415, 3415f
- release/transposition, elbow loss of motion, 177
- TEA and transposition of, 3431, 3431f
tethering, release, 1383, 1383f, 1384f
- transposition, elbow contracture release and, extrinsic, 3417

Ulnar nerve at Guyon’s canal

- anatomy, 2671, 2672f
- compression, 2671–2675
differential diagnosis, 2674
- natural history of, 2672
- nonoperative management of, 2674
- pathogenesis of, 2671–2672, 2673f, 2673f
- patient history of, 2672–2673
- physical findings in, 2672–2673
- surgical management of, 2674
decompression, 2671–2675
- complications of, 2675
- outcomes of, 2675
- pearls and pitfalls of, 2675
- postoperative care of, 2675
- techniques for, 2674–2675, 2675f
diagnostic studies, 2673–2674
exploration of, 2674–2675, 2675f
- imaging, 2673–2674

Ulnar nerve palsy

- anatomy and, 2716
- definition, 2716
- diagnostic studies, 2716–2717, 2717f
- natural history, 2716
- nonoperative management, 2717
- pathogenesis, 2716
- patient history, 2716–2717
- physical findings, 2716–2717, 2717f
- surgical management, 2717–2718
- tendon transfers, 2716–2722
- claw deformity of fingers and, 2720–2721, 2721f
- complications of, 2722
- flexor digitorum profundus, 2721
- outcomes of, 2722
- pearls and pitfalls of, 2721
- postoperative care of, 2721–2722
- thumb adduction restoration, 2718–2720, 2719f, 2720f

Ulnar osseous groove, ECU subluxation and deepening, 2648, 2648f

Ulnar shaft fractures

- distal, ORIF for, 2232, 2232f
- surgical management, 2228–2229, 2228f

Ulnar shortening

- osteotomy, 2864–2873
- anatomy and, 2864–2865, 2864f
- AO compression device for, 2871, 2871f
- author’s preferred technique for, 2868–2870, 2868f, 2869f, 2870f
- complications of, 2873
- osteochondroma, 2871–2872, 2872f
- outcomes of, 2873
- pearls and pitfalls of, 2872–2873, 2872f
- postoperative care of, 2873

TFCC, arthroscopically assisted, 2857–2862
- complications of, 2862
- outcomes of, 2862, 2862f

Ulnar slip excision, flexor digitorum superficialis, A1 pulley release for trigger finger with/without, 2650–2656

Ulnar styloid fractures

- anatomy and, 2172, 2224, 2225f
- arthroscopic reduction/fixation of, 2172–2181
- complications for, 2181
- metacarpal comminution for, 2178–2180, 2178f, 2179f
- outcomes for, 2181
- pearls and pitfalls for, 2180–2181
- postoperative care for, 2181
- techniques, 2176, 2176f, 2180, 2180f
- definition, 2172
- diagnostic studies, 2173–2174
differential diagnosis, 2174
- imaging, 2173–2174, 2174f
- natural history, 2172–2173
- nonoperative management, 2174
- ORIF, 2224–2232
- techniques for, 2230, 2231f
- pathogenesis, 2172
- patient history, 2173
- physical findings, 2173
- surgical management, 2174–2175, 2175f, 2226, 2227f
- TFC tear open repair, peripheral with, 2525, 2525f

Ulnar styloid nonunion

- ORIF, 2231
- surgical management, 2228, 2228f

Unicameral bone cyst (UBC), 1345–1350

- imaging, 1346, 1346
- definition, 1345
- natural history, 1345
- nonoperative management, 1347
- outcomes, 1350
- pathogenesis, 1345
- patient history, 1345–1346
- pearls and pitfalls, 1350
- physical findings, 1345–1346
- postoperative care, 1350
- surgical management, 1347–1349, 1347f, 1348f, 1349f

Unicondylar knee arthroplasty (UKA), 895–904

- anatomy and, 895
- balancing flexion and extension gaps, 899f
- complications, 903–904, 903f
- definition, 895
- diagnostic studies, 895–896
differential diagnosis, 896
- drilling, 898–899, 899f
- exposure, 897, 897f
- final component in, inserting/cementing, 901f, 902f
- imaging, 895–896, 895f
- natural history, 895
- nonoperative management, 896
- outcomes, 902–903, 903f
- pathogenesis, 895
- patient history, 895
- pearls and pitfalls, 902
- physical findings, 895
- posterior condyle resection and milling, 899, 900f
- postoperative care, 902, 902f
- surgical management, 896–897, 897f
- techniques, 897–902
- templating, 898–899, 899f
tibial resection, 897–898, 898f
- trial bearing, 901, 901f
- trial component, 901, 901f
- Unit rod instrumentation, 1448–1457

- for neuromuscular scoliosis, 1448–1457
- completion/wound closure for, 1455, 1455f, 1456f
- complications of, 1457
- exposure and, 1452
- Luque wire passage and, 1453, 1453f
- outcomes of, 1454
- pearls and pitfalls of, 1456
- pelvis preparation and, 1452, 1452f
- postoperative care of, 1457
- rod selection/insertion and, 1454–1455, 1454f, 1455f

Upper cervical spine, 1399

- instability, 1400–1402

Upper extremity surgery

- anesthetic considerations for, 2102–2113
- background of, 2102
- complications of, 2111–2113, 2111f
- equipment and, 2108–2109, 2109f
- informed consent and, 2110
- pain management and, 2109–2110, 2109f, 2110r
- preoperative evaluation of, 2102–2103, 2102r, 2103f, 2103r
- regional anesthesia and, 2104–2108, 2104r, 2105f, 2106f, 2107f, 2108f
- selection of anesthesia and, 2104, 2104f
- trauma, 2102–2103
- pediatric, anesthetic considerations for, 2103, 2103f, 2103r

Ureter, 1856

Urethography, retrograde, ORIF, sacrum/SL joint, 491

Urine retention, anesthesia and, 2111
primary incision/excision on volar side for, 2343, 2433/4
volar plate, detachment and, 2433, 2433/4
volar plate, securing and, 2435, 2435/6
volar plate, transposing and, 2434, 2434/5
Volar plating, distal radius fracture, 2206–2216
anatomy and, 2206–2207, 2206/f
complications of, 2216
definition of, 2206
fixed-angle, 2209–2214, 2210f, 2211f, 2212f, 2213f, 2214f
fixed-angle, using plate as reduction tool, 2213, 2215f
outcomes of, 2216
pears and pitsalls of, 2215–2216
postoperative care of, 2216
Volar radial (VR) portal, arthroscopy
DRCI repair, 2546, 2547/f
hand/wrist, 2123
hand/wrist midcarpal, 2124
Volar rim fragment, fragment-specific fixation
and, 2193–2194, 2194/f
Volar wrist. See also Wrist
ganglion cyst, 3016–3017, 3016
VPA. See Volar plate arthroscopy
VR portal. See Volar radial portal
V-Y advancement, Achilles tendon ruptures, chronic, 4398–4405
complications of, 4405
outcomes of, 4405
pears and pitsalls of, 4404
postoperative care of, 4404
V-Y advancement flap
lateral, finger tip amputation, 2935, 2935/f
volar, fingertip amputation, 2935, 2935/f
V-Y lengthening, Achilles tendon ruptures, chronic, 4400–4401, 4401/f
V-Y quadricepsplasty, 987, 987/f
V-Y quadruplasty, revision TKA with extensive exposure and, 986–988
complications of, 988
definition of, 986
outcomes of, 986
pears and pitsalls of, 987
postoperative care for, 987–988
quadricepss turndown and, 986, 987/f
standard approach to, 986
tibial tubercle osteotomy and, 986
V-Y quadricepsplasty and, 987, 987/f
pathogenesis, 3707
patient history, 3707–3708, 3708/f
pears and pitsalls of, 3712
physical findings, 3707–3708, 3707/f
postoperative care of, 3713, 3713/f
surgical management, 3708–3711, 3709/f–3711/f
approach, 3708
exposure of metatarsal, 3709–3710, 3709/f–3710/f
fixation of mobile fragment, 3711, 3711f
osteotomy and bony slice extraction, 3710, 3710f–3711/f
positioning, 3708
preoperative planning, 3708, 3709/f
Williams rod, congenital pseudarthrosis
repair with, tibial, 1251–1257, 1254, 1255/f
Wiltse osteotomy, 1281.
Wagner plate fixation.
Wagner type osteotomy, 859.
Watson-Jones approach, ORIF, 526–528, 527/f
Weber clamp reduction, ORIF, symphysis, 480, 481/f
Weil lesser metatarsal shortening osteotomy
anatomy, 3707
complications of, 3713
definition, 3707
diagnostic studies, 3708
differential diagnosis, 3708
imaging, 3708, 3708/f
natural history, 3707
nonoperative management, 3708
outcomes of, 3712–3713
dorsal druji portal for, 2125
4-5 portal for, 2125/f
midcarpal radial portal for, 2122
midcarpal ulnar portal for, 2123
nonoperative management and, 2118–2119, 2119r
1-2 portal for, 2122, 2122/f
pears and pitsalls of, 2123
postoperative care of, 2125
68/6U portals for, 2121
surgical management and, 2119–2121, 2120f, 2120r
TFCC and, 2523, 2523/f
3-4 portal for, 2121
volar druji portal for, 2125
volar ulnar portal for, 2124, 2124/f
VR portal, midcarpal for, 2124
VR portal for, 2123
arthrosis
definition of, 2791
diagnostic studies for, 2792
differential diagnosis of, 2792
imaging of, 2792
natural history of, 2791
nonoperative management of, 2792
pathogenesis of, 2791
patient history of, 2791, 2791/f
physical findings of, 2791, 2791/f
surgical management of, 2792
definition, 2081
degeneration, 2802–2803, 2802/f
natural history of, 2817
patient history of, 2817
physical findings of, 2817
wrist implant arthroplasty and, 2823–2824, 2825/f
denervation, 2791–2794
complications of, 2794
full, 2792–2793, 2792/f, 2793/f
outcomes of, 2794
partial, 2792
pears and pitsalls of, 2794
postoperative care of, 2794
extension restoration, 2724, 2724r
innervation, 2791
ligament injuries
natural history of, 2808
pathogenesis of, 2808
patient history of, 2808
physical findings of, 2808
nerve injury, 2691–2692
diagnostic studies for, 2693
differential diagnosis of, 2693
imaging of, 2693
nonoperative management of, 2693
patient history of, 2692, 2692/f
physical findings of, 2692, 2692/f
surgical management of, 2693
nerve transection, complete
approach to, 2693–2694, 2694/f
cable graft repair following, 2695, 2695/f
complications of, 2698
cordur repair following, 2696, 2696/f
epineural repair following, 2694, 2694/f
group fascicular repair following, 2695, 2695/f
nerve grafting following, 2691–2698
outcomes of, 2697–2698
pears and pitsalls of, 2697
postoperative care of, 2697
primary repair following, 2691–2698
vascularized nerve graft repair following, 2696, 2696/f
nerve transection in, complete, 2691–2698
Wrist (continued)
proximal row, anatomy, 2802
septic arthritis
anatomy of, 2917, 2917f
arthroscopic débridement for, 2921, 2921f
aspiration of, 2920
diagnostic studies for, 2918
differential diagnosis of, 2919
imaging of, 2918, 2918f
natural history of, 2918
nonoperative management of, 2919
pathogenesis of, 2917–2918, 2918f
patient history of, 2918
physical findings of, 2918
surgical drainage, open of, 2921–2922, 2922f
surgical management of, 2919
surgical treatment of, 2917–2923
surgical treatment of, techniques for, 2919–2922, 2920f, 2921f, 2922f
surgical approaches, 2081–2089
pearls and pitfalls of, 2089
surgical management, 2082
Wrist extensor tendon disruption, traumatic, repair following, 2578–2587
complications of, 2587
outcomes of, 2587
pearls and pitfalls of, 2586–2587
postoperative care of, 2587
suture techniques for, 2582, 2582f
techniques for, 2584–2586, 2585f, 2586f
Wrist flexion deformity
anatomy, 1371
definition, 1371
diagnostic studies, 1372
differential diagnosis, 1372
FCU transfer for, 1371–1375
complications of, 1374–1375
outcomes of, 1374
pearls and pitfalls of, 1374
postoperative care of, 1374
imaging, 1372
nonoperative management, 1372
pathogenesis, 1371
patient history, 1371–1372
physical findings, 1371–1372
surgical management, 1372–1373, 1373f
Wrist implant arthroplasty, 2822–2830
anatomy and, 2823, 2823f
complications of, 2830
definition, 2822–2823, 2822f
Maestro prosthesis, 2824–2828, 2825f, 2826f, 2827f, 2828f, 2829f
outcomes of, 2829–2830, 2830f
pathogenesis and, 2823, 2823f
pearls and pitfalls of, 2829
postoperative care of, 2829
wrist degeneration and, 2823–2824, 2823f

X
Xenograft, 2941

Z
Z-plasty, 2964–2965, 2964f, 2965f
contractures bands, release of, 2968–2969, 2968f, 2969f
Z-plasty flaps, 2954, 2958, 2958f
